Major advances have been made in the science of nanophase materials, and significant progress has been made on the technological front. In particular, impressive improvements have been made in the high rate processing of nanopowders at a competitive cost. Looking ahead, major innovations can be expected in the preparation of high-performance nanophase coatings and consolidated parts. The most immediate pay-off should be in the processing of thermally sprayed WC/Co-base coatings and liquid-phase sintered parts. On the other hand, in view of recent advances in high-pressure consolidation of nanoceramic powders, it is evident that within a few years, commercialization of sintered nanophase ceramics will be realized.

The use of nanopowder in dispersed form is an established technology in the catalysis industry. Further improvements in catalytic performance can be expected as a consequence of the ability now to produce nanoparticles that are tailored with respect to composition, structure, and morphology. In addition, dispersing nanoparticles in fluid media presents new opportunities that are being intensely pursued. A good example is the use of aqueous suspensions of monodispersed ceramic nanoparticles as abrasive medium for planarization of semiconductor and optical devices.

1. Introduction

The terms “on-line monitoring” and “process analytical chemistry” are often used synonymously. They are gaining increasing attention and importance in both industry and academia. The extent of agreement between the two terms is indeed very broad in that they provide sufficiently accurate and immediate information on variables that describe the state of a chemical reaction.

On-line monitoring of reactions encompasses on-stream and on-reactor application of analytical methods to monitor the chemical composition of a reaction mixture, to identify process-related chemical species, and to quantify the concentration of reaction ingredients, products and byproducts. In addition to revealing the state of the reactor, on-line analysis of physical parameters (temperature, pressure, level, density, viscosity, etc.) may also reflect the extent of a chemical reaction.

Process analytical chemistry comprises applications which supply relevant process information of interest “in-time”: The time for sampling and analysis is very short compared to the overall reaction time and thus allows adequate monitoring and efficient control of the reaction. The utilization of the analytical data for control strategies makes process analytical chemistry an essential integral part of process engineering and control systems (see ⟶ Process Control Engineering; ⟶ Chemical Plant Design and Construction).

Process analytical methods may be classified as off-line, at-line, on-line, or in-line with respect to sampling, sample transport, and analysis itself (Table 1) [1]. There is no clear-cut line between the different classes, and the boundaries are even moving: “Some of today's off-line techniques may become tomorrow's on-line techniques” [2]. An increasing number of off-line techniques have been converted into on-line methods by automated, robot-assisted withdrawal of samples from the reactor or from bypass or process streams and feeding them into off-line instruments.

Table 1. Classes of process analyzers (adapted from [1])

Process analyzer	Sampling	Sample transport	Analysis
Off-line	manual	to remote or centralized laboratory	automated/manual
At-line	discontinuous/manual	to local analytical equipment	automated/manual quick check
On-line	automated	integrated	automated
In-line	integrated	no transport	automated
Noninvasive	no contact	no transport	automated

On-line monitoring and control of chemical reactions contributes to:

- Guaranteeing and improving product quality and consistency (i.e., repeatability of product properties within narrow specification ranges)
- Increasing the efficiency of the process
- Ensuring safe reactor operation by monitoring process and reactor parameters
- Understanding fundamentals of the reaction itself
- Saving time for analysis and sample transport
- Reducing emissions by avoiding sample withdrawal and transport
- Reducing costs for labor, raw materials, off-spec products, and process waste

In most cases, purchasing and installation costs of on-line and in-line analytical instruments exceed those of off-line equipment, but as soon as the measurements required exceed a certain (relatively small) number per day, on-line analysis becomes superior to off-line analysis (Fig. 1). However, the real savings of on-line reaction monitoring are due to improved process efficiency, lower raw materials consumption and waste generation, and, most important, the ability to manufacture high-quality products.

Figure 1. Total costs for on-line and off-line process analyses (including instrument costs, labor costs, energy, material, etc.)

A) Costs for purchase of off-line instruments; B) Costs for purchase and installation of on-line equipment

Several issues have to be addressed when designing an on-line analysis application [1], [3-8]:

- Information necessary to monitor and control the process (physical parameters, chemical composition, etc.)
- Frequency of measurements with respect to the timescale of the reaction
- Average values, typical fluctuations, dynamic ranges and expected extremes of properties
- Type, precision, and response time of sensors
- Robustness of sensors and simplicity of installation
- Full automation and minimum maintenance of equipment
- Number (combination) of sensors and location of measurement
- Proper sampling and, if required, sample conditioning
- Form of data output and further handling of information
- Compatibility with process control system
- Safety precautions and possible hazards
- Costs of instrumentation and availability of trained personnel

Demands on performance characteristics of on-line analytical techniques differ for academic research applications, process development and pilot plant operation, and monitoring of industrial manufacturing processes, as summarized in Table 2 (see also ⟶ Analytical Chemistry: Purpose and Procedures; ⟶ Chemometrics; ⟶ Plant and Process Safety; ⟶ Polymerization Processes; ⟶ Process Control Engineering; ⟶ Process Development; ⟶ Sampling).

Table 2. Relative importance of various performance characteristics of on-line analyses in academic research, process development, and industry [9]

Characteristics	Academic research	Process development	Manufacturing
High accuracy	+++	+++	+++
Good reproducibility	+++	+++	+++
Good selectivity	+++	+++	+++

* Process-dependent. +++ Very important, ++ important, + not very important.

The number of textbooks introducing the field of process analytical chemistry is still limited [4], [6-8], [10-15]. Since 1993 a series of review articles on the progress in process analytics have been published [16-21]. On-line monitoring techniques play a major role in the contents of several scientific journals such as Journal of Process Analytical Chemistry [22], Applied Spectroscopy [23], Analytical Chemistry [24], and Analytical and Bioanalytical Chemistry [25]. Several international conferences devoted solely to process analytics have been established over the years. The most importants ones are IFPAC (International Forum for Process Analytical Chemistry [26]), APACT (Advances in Process Analytics and Control Technology [27]), and PREACH (Process Related Environmental Analytical Chemistry [28]). The reader should also be aware of the process analytical technology initiative of the FDA [29] which is of crucial importance to the pharmaceutical industry. Academic as well as academic-industrial consortia drive the development of new, more reliable and cost-effective techniques for on-line monitoring of chemical reactions applicable to the industry. The most active ones are CPAC (Center for Process Analytical Chemistry, Seattle, USA [30]), MCEC (Measurement and Control Engineering Center, Knoxville

USA [31]), CPACT (Center for Process Analytics and Control Technology, Newcastle, Strathclyde, Hull, UK [32]), MACC McMaster Advanced Control Consortium, Hamilton, Canada [33]), and CTAC (Control Theory and Applications Center, Coventry, UK [34]). A Working Group on Process Analytical Chemistry of the Society of German Chemists (GDCh, Frankfurt/M, D [35]) has been founded in 2005.

[Top of Page]

2. Reaction Calorimetry

2.1. Introduction

The majority of chemical processes are accompanied by temperature changes of the reaction mixture owing to release or consumption of heat in the course of the reaction. Heat evolution is a definite, reproducible, and directly measurable characteristic of a chemical reaction. This enables one to monitor the extent of a reaction by measuring temperature or heat flux changes (see [36-47] and ⟶ Plant and Process Safety for introduction, overviews, applications, and related subjects).

Reaction calorimetry is noninvasive, rapid, accurate, robust, and, as it is based on temperature measurements, relatively easy to carry out. Temperatures can be measured directly within the reaction mixture (reactor interior), at the reactor/exterior interface (reactor wall), or in the heating/cooling liquid of the reactor jacket.

An advantage of reaction calorimetry is that the heat of reaction Q_r derived from temperature measurements is directly proportional to the rate of reaction. This allows easy access to basic kinetic and thermodynamic data of chemical reactions.

With reaction calorimetry, rates of reaction or conversion of reactants can be determined quasi-instantaneously and continuously with a high degree of resolution. This makes reaction calorimetry an ideal tool for real-time feedback control of chemical composition during the course of reaction.

Reaction calorimetry not only provides quantitative information on the chemical process itself (e.g., heat of reaction, reaction rate, conversion) but also on reactor parameters necessary for safe reactor operation and process design:

- Global reaction kinetics
- Heat production rates
- Necessary cooling power
- Reactant accumulation
- Adiabatic temperature rise to avoid runaway reactions
- Heat-transfer coefficients for scale-up

However, reaction calorimetry is a nonselective method. It is impossible to distinguish between parallel chemical reactions with heat generation and simultaneous enthalpic processes within the system such as phase transitions, crystallization, mixing, and dissolution.

2.2. Heat Flow Balance and Principles of Measurement

2.2.1. *Heat Flow Balance*

The basis for reaction calorimetry is the energy balance around the reactor. Sources and sinks of heat Q_i which contribute to the overall heat flux balance (Eq. 1) are shown schematically in Figure 2:

Figure 2. Schematic of a reaction calorimeter

$$\sum_i \dot{Q}_i = 0 \tag{1}$$

The quantity of interest in reaction calorimetry is the heat flux Q_r generated by chemical reactions within the reactor

$$\dot{Q}_r = V_R \sum_j r_j(-\Delta H_{r,j}) \tag{2}$$

where V_R is the volume of the reaction mixture, r_j the rate of reaction j, and $\Delta H_{r,j}$ the reaction enthalpy of reaction j. For typical heats of reaction, see ⟶ Plant and Process Safety.

Different rates of heat generation within the reactor and heat flow out of or into the reactor lead to temperature changes of the reaction mixture. This accumulated heat Q_{acc} is a major cause of uncertainty and error in quantitative analysis of reaction calorimetry data because it depends on the derivative of the reactor temperature T_R

$$\dot{Q}_{acc} = C_{p,tot}\dot{T}_R \tag{3}$$

where $C_{p,tot}$ is the heat capacity of the filled reactor (reactor plus reaction mixture).

Feeding of material into the reactor with a mass flow rate dm_k/dt (and also withdrawal of material from the reactor) leads to a heat flux dQ_{feed}/dt

$$\dot{Q}_{feed} = \sum_k \dot{m}_k c_{p,k}(T_k - T_R) \quad (4)$$

where $c_{p,k}$ is the specific heat capacity of the kth reactor feed and T_k its temperature.

The heat input by stirring the (viscous) reaction mixture Q_{stir} is given by

$$\dot{Q}_{stir} = P_0 N_v^3 d_{stir}^5 \varrho_{mix} \quad (5)$$

where P_0 is the power number, N_v the stirrer speed, d_{stir} the diameter of the stirrer, and ϱ_{mix} the density of the reaction mixture.

The energy balance of the reactor is also influenced by heat losses to the surroundings Q_{loss} (e.g., by conduction or radiation). It is important to identify and quantify all possible sources of heat losses around a reactor because heat losses might be significantly larger (2 – 5 times) than Q_{acc}, Q_{stir}, or Q_{feed}. In most cases, heat losses must be determined by separate experiments prior to the reaction or without a running reaction.

Additional heat can be removed by the insertion of reflux condensers into the reactor. The heat flow over the reflux condenser can be calculated according to Equation

$$Q_{reflux} = m_{cool} c_{p,cool}(T_{cool,in} - T_{cool,out}) \quad (6)$$

where $\dot{m}_{cool}$ is the coolant mass flow through the condenser, $c_{p,cool}$ is the specific heat capacity of the coolant, and $T_{cool,in} - T_{cool,out}$ the temperature difference across the condenser.

For calibration purposes (see below), heat may also be generated by additional heaters

$$\dot{Q}_{cal} = UI \quad (7)$$

where U and I are the voltage and current of the electrical heater, respectively.

The quantity that is actually measured in a calorimetric experiment is the heat flux through the reactor wall to the cooling/heating system Q_{trans}. There are two main methods to determine Q_{trans}: heat flux calorimetry and heat balance calorimetry.

Heat Flux Calorimetry. In heat flux calorimetry, the generated heat is measured by means of the temperature difference between reactor and jacket. The heat transfer between reactor interior and jacket medium Q_{trans} depends on the overall heat transfer coefficient k_Q through the wall, the heat exchange area of the reactor wall A_R that is actually in contact with the reaction mixture ("wet area"), and the difference between reactor temperature and mean jacket fluid temperature $\bar{T}_J$

$$\dot{Q}_{trans} = k_Q \cdot A_R(\bar{T}_J - T_R) \quad (8)$$

Typically, the temperature difference is sufficiently large for heat flux calorimetry to be very sensitive.

Advantages of heat flux calorimetry are its (i) high sensitivity because of the (relatively large) temperature difference between reaction medium and jacket fluid, (ii) fast response and high accuracy, and (iii) its independence on the flow rate of the jacket medium.

The reactor area for heat exchange with the jacket A_R is almost constant for batch reactions. There can be some variation in A_R as a result of density changes of the medium during the course of the reaction. In semibatch reactions, A_R is no longer a constant. Feeding of reaction components into the reactor leads to an increase of its filling level. If the feeding rates are known their influence on A_R can be taken into account.

A major problem in heat flux calorimetry is the determination of the exact k_Q value. The overall heat transfer coefficient may change considerably during the course of the reaction because it depends on, for example, the mixture's viscosity and density, the stirring rate (hydrodynamics of the reactor), and heat transfer through the reactor/jacket interface (influence of film formation or reactor fouling). Hence, $k_Q A_R$ must be calibrated separately in a typical heat flux calorimetry experiment. Several variations are proposed in the literature and offered by instrument manufacturers:

Continuous calibration during the reaction can be achieved by application of well-defined heat pulses produced by a calibration heater. The reactor heat measured with these pulses enables one to quantify the heat of reaction. However, the hot surface of the calibration heater may also cause problems with temperature-sensitive samples (e.g., product degradation, film formation).

REICHERT [48], [49] developed an elegant method to overcome the problem of variations in $k_Q A_R$, known as temperature oscillation calorimetry. A small sinusoidal temperature change is added to the overall temperature/time characteristic of the reactor via the jacket liquid or a calibration heater. These forced temperature oscillations

$$\dot{Q}_{\mathrm{osc}} \sim (1 + \sin(\omega t)) \tag{9}$$

create temperature oscillations of the reactor with amplitude δT_R and frequency $\omega = 2\pi/\tau$, where τ is the oscillation period. Decoupling and separate determination of oscillating and nonoscillating terms in the energy balance equation allows the simultaneous on-line calculation of the rate of reaction as well as the heat transfer value of the reactor $k_Q A_R$:

$$k_Q \cdot A_{\mathrm{R}} = -\omega C_{p,\mathrm{mixture}} \frac{\delta T_{\mathrm{R}} \sin \varphi_{\mathrm{r}}}{\delta T_{\mathrm{J}} - \delta T_{\mathrm{R}} \cos \varphi_{\mathrm{r}}} \tag{10}$$

where φ_r is the phase shift between the oscillations, and δT_J the amplitude of temperature oscillations of the jacket liquid. Temperature oscillation calorimetry has been critically reviewed and compared to conventional calorimetry in [50], [51].

One- or Two-Point Calibration. In the case of a constant heat transfer coefficient during the reaction the heat transfer value $k_Q A_R$ can be determined by calibration before the start of the reaction.

Several commercially available calorimeters apply a two-point calibration. The first calibration must be carried out before the reaction run starts to determine an initial value of $k_Q A_R$. A second calibration after completion of the reaction in combination with the assumption of a linear behavior between start and end calibration allows one to back-interpolate the reaction data after the end of the reaction.

However, the reactor/jacket interlayer is prone to film formation and precipitation of reaction products or byproducts, and the viscosity of the reaction mixture may change dramatically in a short time interval, all of which can alter k_Q by orders of magnitude at a certain time (not continuously). Hence, interpolation is inaccurate, and even pre- and post-calibration of k_Q by separate experiments may lead to erroneous results.

Absolute Heat Flux Calibration. Absolute heat flux calorimetry (ChemiSens AB, Lund, Sweden) relies on the fact that the thermal conductivity λ_Q within the reactor wall is constant throughout the reaction, in contrast to the overall heat transfer coefficient k_Q through the wall (wall + interlayers). Calorimeter calibration can be carried out by utilizing the temperature gradient $(T_1 - T_2)/d$ (see Fig. 3). Thus, the heat flux can be calculated according to

$$k_Q \cdot A_{\mathrm{R}}(T_{\mathrm{J}} - T_{\mathrm{R}}) = \frac{\lambda_{\mathrm{Q}}}{d} A_{\mathrm{R}}(T_1 - T_2) \tag{11}$$

Figure 3. Absolute Heat Flux Calorimetry: Schematic of reactor wall temperature gradient (reproduced by permission of ChemiSens AB, Lund, Sweden)

Note that the immediate vicinity of the reactor wall to both sides (i.e., reaction mixture and jacket liquid) may behave like an additional thin film characterized by other distinct heat transfer resistances.

Heat Balance Calorimetry. An alternative approach for measuring the heat generated within the reactor is to determine the total heat balance of the cooling/heating liquid circulating through the jacket:

$$\dot{Q}_{\mathrm{trans}} = \dot{m}_{\mathrm{liq}} c_{p,\mathrm{liq}} (T_{\mathrm{J,in}} - T_{\mathrm{J,out}}) \tag{12}$$

where $c_{p,\mathrm{liq}}$ is the specific heat capacity of the jacket liquid. In this case, Q_{trans} is independent of both heat exchange area and heat transfer coefficient. However, it depends on the circulation rate $\dot{m}_{\mathrm{liq}}$ of the jacket liquid. Heat losses at the outer jacket wall directly influence the heat balance of the circulating liquid.

Heat balance calorimetry is relatively slow and insensitive compared to heat flux calorimetry because of the small temperature difference $T_{\mathrm{J,in}} - T_{\mathrm{J,out}}$. This also leads to stricter requirements with respect to the accuracy of temperature measurements. To achieve 0.5 W resolution, it is necessary to measure the temperature with an accuracy of about 0.001 K (compared to 0.05 K in heat flux calorimetry for the same resolution). Under typical conditions, energy resolution in heat balance calorimetry is on the order of 2 W, compared with 0.5 W in heat flux calorimetry.

Heat Compensation Calorimetry. In heat compensation calorimetry, both the vessel temperature T_R and the jacket-fluid temperature T_J are fixed with $T_J < T_R$. Heat from an additional electrical heater Q_{el} is supplied to the mixture to maintain the temperature T_R of the reactants. After the reaction has been started and a heat Q_r released, the electrical power Q_{el} is reduced to hold T_R constant. This reduction in Q_{el} is equal to the reaction heat Q_r under the condition that $k_Q A_R$ and the heat losses Q_{loss} are constant throughout the reaction.

As in heat flux calorimetry, the unknown and changing quantity $k_Q A_R$ requires calibration of the calorimeter. The hot

surface of the electrical heater is prone to the formation of films, coatings, precipitates, and hot spots.

2.2.2. *Basic Modes of Operation*

From a thermodynamic point of view, three basic modes of operation in heat flux calorimetry can be distinguished: adiabatic, isoperibolic, and isothermal calorimetry.

Adiabatic Reaction Calorimetry. An adiabatic reaction calorimeter is characterized by thermal insulation of the reaction mixture from the surroundings. As a result, the heat released during the reaction is stored within the reaction mixture. Thus, the temperature gradient of the reaction mixture directly reflects the ongoing reaction, and the total heat balance is simply given by (cf. Eq. 13):

$$\dot{Q}_r = C_{R,tot}\dot{T}_R \tag{13}$$

In practice, thermal insulation of the reaction mixture can be achieved either by means of an infinitely large thermal resistance between mixture and surroundings (e.g., Dewar calorimeter with evacuated reactor jacket) or by continuously matching the jacket temperature to that of the mixture such that there is no heat transfer through the reactor/jacket wall ($T_J(t) = T_R(t)$).

A major disadvantage of adiabatic reaction calorimetry is the interdependence of mass balance and heat balance via the reaction rate, which requires an adequate kinetic model for data analysis.

Isothermal Reaction Calorimetry. In isothermal reaction calorimetry, the reaction mixture temperature T_R is held constant, for example, by adjusting the temperature of the jacket fluid T_J or by controlling the power of a compensation heater. In practice, it is very difficult to keep the reactor strictly isothermal because of the nonzero heat transfer resistance of the reactor wall and deviations and delays in power control. Thus, heat accumulation must be taken into account in the isothermal heat balance

$$\dot{Q}_r = k_Q A_R(T_R - \bar{T}_J) + C_{p,total}\dot{T}_R \tag{14}$$

Isoperibolic reaction calorimetry is opposite to isothermal calorimetry in the sense that the jacket temperature T_J is held constant instead of the reactor temperature T_R. As a consequence, T_R changes during the reaction. Heat is both accumulated in the reaction mixture and transferred to the jacket liquid. Hence, the heat balance can be described as in isothermal calorimetry (see Eq. 14).

2.3. Applications and Instrumentation

The heat of reaction $Q_r(t)$ can be calculated according to Equation 1 if all contributions Q_i to the overall heat balance of the reactor are measured or known. If only one exothermic chemical reaction proceeds in the vessel, the reaction rate is given by Equation 2, and the actual relative calorimetric conversion $X_r(t)$ is given by Equation 15

$$X_r(t) = \frac{\int_0^t Q_r(t)\mathrm{d}t}{\int_0^{t,\mathrm{final}} Q_r(t)\mathrm{d}t} \tag{15}$$

On-line calorimetry has been used by chemical companies to monitor the extent of reactions for several decades [52-57]. Industrial-scale reactors have a relatively low ratio of heat-exchange surface area to volume compared to bench-scale reactors and calorimeters; hence, their heat-removal capacity is limited. To achieve a maximum production rate in industrial-scale reactors, the reaction rate should be matched to the heat-removal capacity throughout the reaction. On-line reaction calorimetry provides some of the data necessary for a desired reaction run and safe reactor operation (e.g., heat release rates, heat losses, reaction rate, conversion).

Reaction calorimetry has been used to monitor polymerization reactions and crystallization processes [58-60]. Strategies for on-line control and optimization of reactions on the basis of calorimetric measurements during the course of the reaction have been described [61-67]. Reaction calorimetry is the method of choice for studying thermal runaway reactions [68] (see ⟶ Plant and Process Safety). The application of calorimetry to investigating the kinetics of reactive blending and reactive extrusion is discussed in [69], and the application of adiabatic temperature rise for monitoring reaction injection molding (RIM) in [70]. On-line calorimetric data can be used to predict final product properties by means of multivariate statistics [71] or neural networks [72].

Most instrument suppliers (e.g., Mettler-Toledo, ChemiSens, HEL) offer computer-controlled calorimeters that can be run in different modes (Figure 4). The nonselectivity of reaction calorimetry in monitoring complex reactions (e.g., reactions in which parallel processes occur, copolymerizations, etc.) can be overcome by combining calorimetry with other on-line methods to obtain additional information. These methods include density, pressure, gas chromatography, dielectric spectroscopy, conductometry [73], and infrared [74], [75] and Raman spectroscopy [76] (Fig. 5; ⟶ Infrared and Raman Spectroscopy).

ChemiSens AB, Lund, Sweden)

Figure 5. Reaction calorimeter RC1 equipped with React IR Infrared Spectrometer (ASI Applied Systems) for simultaneous on-line calorimetry and infrared analysis (courtesy of Mettler-Toledo GmbH, Analytical)

Calorimetric data of chemical reactions have also been determined by differential scanning calorimetry [77-80] (see ⟶ Plastics, Analysis; ⟶ Plastics, Properties and Testing).

3. Ultrasonic Methods

3.1. Introduction

The propagation of ultrasound in matter is a physical effect that is receiving increasing attention for on-line monitoring of chemical processes. Ultrasonic methods are easy to use, safe, nondestructive, and noninvasive. Signal response times on the order of milliseconds allow real-time monitoring of fast reactions.

In most applications, ultrasound is generated by piezoelectric transducers. Because of the reversibility of the piezoelectric effect, the transducers can act both as emitters and receivers of ultrasonic waves. Depending on the requirements of the application, a wide variety of readily available and cost effective piezoelectric materials can be utilized as transducers (e.g., quartz, lithium niobate, barium titanate, poly(vinylidene fluoride), zinc oxide).

Ultrasonic sensors and ultrasonic systems for materials characterization, process monitoring, and applications in chemistry are reviewed in [81-88].

3.2. Theory

A planar elastic ultrasonic wave can be described by its complex alternating pressure $p(x,t)$ as a function of time t and distance x (Eq. 16)

$$p(x,t) = p_0 \exp\left[i\omega\left(t - \frac{x}{u}\right)\right] \cdot \exp\left[-\alpha x\right] \tag{16}$$

where $\omega = 2\pi f$ (f = frequency), p_0 is the pressure amplitude, and u and α are the velocity and attenuation of sound in matter. The frequency of ultrasound waves is in the range of 20 kHz to about 1 GHz with corresponding wavelengths on the order of 1.6 cm to 0.3 µm in air ($u \approx 330$ m/s), 6 cm to 1.2 µm in liquids ($u \approx 1200$ m/s), and 20 cm to 4 µm in solids ($u \approx 4000$ m/s).

Both u and α strongly depend on the material's state and properties. In solids, the longitudinal and transverse sound velocities $u_{l,sol}$ and $u_{tr,sol}$ are related to the bulk modulus K, the shear modulus G, and the density ϱ according to

$$u_{l,sol}^2 = \frac{K + \frac{4}{3}G}{\varrho} \text{ and } u_{tr,sol}^2 = \frac{G}{\varrho} \tag{17}$$

The longitudinal ultrasonic velocity in liquids $u_{l,liq}$ depends on both the adiabatic compressibility β of the liquid and its density (Eq. 18).

$$u_{l,liq}^2 = \frac{1}{\beta\varrho} \tag{18}$$

Ultrasonic shear waves in liquids ($u_{tr,liq}$) do not propagate significantly. They are strongly dampened, and therefore not of technical importance.

The sound attenuation α of solids and liquids depends on several loss mechanisms. Intrinsic, viscous, and thermal losses may contribute to α, as well as scattering and reflection effects at interfaces in heterogeneous samples, relaxation processes in polymers, electrokinetic losses in disperse systems, and structural losses in concentrated systems (e.g.,

pseudoplasticity). Thus, α is influenced by material properties such as density, viscosity, thermal conductivity, expansion, and capacity; by the morphology of the sample (grain size and shape); and by temperature and pressure. It is difficult to derive analytical expressions for α because of its complex dependence on these parameters. However, in simple homogeneous liquid systems, α can be described as

$$\frac{\alpha_{\mathrm{liq}}}{f^2} = \frac{2 \cdot \pi^2}{\varrho \cdot u^3}\left(\frac{4}{3}\eta_s + \eta_v\right) \tag{19}$$

where η_s and η_v are the shear and the volume viscosities of the liquid. Sound is strongly absorbed at high frequencies (f^2 dependence) and cannot penetrate deeply into the material.

A third acoustic parameter of importance with respect to reaction monitoring is the acoustic impedance Z of the material (Eq. 20).

$$Z = \varrho \cdot u \tag{20}$$

It is typically measured in reflection experiments at interfaces by means of the reflection coefficient R (Eq. 21).

$$R = \frac{Z_1 - Z_2}{Z_1 + Z_2} = 1 - T \tag{21}$$

where Z_1 and Z_2 are the acoustic impedances of the materials on both sides of an interface, and T is the transmission coefficient.

A common method for determining acoustic properties is to monitor (compressional) sound pulses travelling over a well-defined distance (Fig. 6). The emitting transducer E generates a sound burst of initial amplitude p_0 (proportional to the applied voltage U_0) which travels a distance x in a time Δt. In multiple-echo mode, Δt is the time delay between successive echoes, and x is twice the distance between transducers. The dampened (and broadened) pulse reaching the receiving transducer R generates an electrical voltage U_x proportional to the pressure amplitude p_x at the receiver. By using this method, sound velocity and attenuation can simply be calculated according to Equations 22 and 23.

$$u = \frac{x}{\Delta t} \tag{22}$$

$$\alpha = \frac{1}{x} \ln \frac{p_0}{p_x} = \frac{1}{x} \ln \frac{U_0}{U_x} \tag{23}$$

Figure 6. Schematic of ultrasonic pulse travelling measurements. (The transducer arrangement can also be used in multiple reflection echo mode.)

Measurements of pulse travelling time are highly accurate and relatively easy to carry out compared to sound attenuation measurements.

The frequency of ultrasonic sensors for reaction monitoring is generally in the 1 – 10 MHz range. In principle, the accuracy of sound velocity measurements is poor for very low frequencies (< 100 kHz) and increases with increasing frequency. However, attenuation does also increase for $f \gg 10$ MHz, and the distance between transducers must be shortened for the signal to reach the receiver. As a result, the accuracy of pulse travelling time measurements also deteriorates at very high frequencies. Typical demands on the accuracy of ultrasonic sensors for reaction monitoring are

$$\frac{\Delta u}{u} \leq 10^{-3} \quad \frac{\Delta \alpha}{\alpha} \approx 0.5\,\% \quad \frac{\Delta Z}{Z} \leq 10^{-3}$$

These conditions imply time measurements in the nanosecond and picosecond range, and of amplitude resolutions of 12 bit and higher [81]. Additionally, temperature control has to be better than ± 0.1 K.

In addition to u and α, other sound wave characteristics (e.g., wave phase φ, resonance frequency f_{res} and shift Δf_{res}) can be measured in certain ultrasonic sensor applications for materials characterization and chemical processes monitoring [81].

3.3. Applications

The basic condition for monitoring chemical processes by means of ultrasound is that physical properties that determine u, α, or Z change during the course of the reaction (see Eqs. 17 – 20). In polymer production and modification, curing and cross-linking reactions, mechanical moduli as well as the mixture's density, compressibility, viscosity, thermal conductivity, etc. alter dramatically, thus influencing sound attenuation and velocity (see Table 3). Hence, those processes are ideal for application of ultrasound to detect the extent of reaction. Even electrochemical processes can be monitored because of the sensitivity of ultrasound to the type of ion and concentration.

Table 3. Ultrasound velocities of monomers and polymers at 20 °C

Substance	Monomer	Polymer
Butyl acrylate	1233 m/s	1375 m/s
Styrene	1354 m/s	2120 m/s
Vinyl acetate	1150 m/s	1853 m/s
Vinyl chloride	897 m/s	2260 m/s

A major advantage of ultrasound (velocity) measurements in industrial applications is the capability to plug the sensor directly into the reacting mixture. They do not necessarily require a sampling loop. Care should be taken because plug-in transducers may cause fouling at their edges or lead to formation of coagula and films. The disturbing influence of gas bubbles in the reaction mixture between the transducers is demonstrated in Figure 7. Monitoring of acoustic impedance *Z* via reflection coefficient measurements may reduce the bubble disturbances. However, so far, no application of *Z* determination in reaction monitoring has been described in the literature.

Figure 7. Influence of gas bubbles on ultrasound velocity measurements during emulsion polymerization

A simple empirical but useful approach for describing the sound velocity of multicomponent reaction mixtures is based on the assumption that each component *i* of the mixture contributes independently to the sound velocity of the mixture u_{mix} according to its concentration c_i

$$u_{mix} = u_0 + \sum_i \left(\frac{\Delta u}{\Delta c}\right)_i c_i \tag{24}$$

where u_0 is the sound velocity of a reference component (e.g., solvent, dispersion medium) whose ultrasonic velocity is either constant throughout the process or changes in a known manner, and $\Delta u/\Delta c$ is the (temperature-dependent) sound velocity – concentration coefficient, which itself may depend on concentration. However, higher order terms are neglected in Equation 24. The influence of component *i* on the sound velocity of component *j* is also neglected. Equation 24 is the basis for on-line concentration measurements in numerous applications in chemistry, biochemistry, and the foods industry.

Ultrasound has been used to monitor chemical reactions since the 1970s [89-92]. Ultrasonic on-line monitoring of polymerization reactions was reported in [93-99]. Crosslinking reactions (curing, gelation) were investigated with ultrasound in [92], [100-106]. As an example, the influence of the extent of reaction of the epoxide ring in a system consisting of the diglycidyl ether of bisphenol A (DGEBA) and 4,4′-diaminodiphenylmethane (DDM) on the ultrasonic velocity and relative ultrasonic absorption is shown in Figure 8. Viscoelastic properties of polymer melts in extruders can be monitored by in-line determination of ultrasonic parameters, along with temperature and pressure measurements [69], [91], [107-111].

Figure 8. Ultrasonic velocity (A) and relative ultrasonic absorption (B), both measured at 1 MHz, as a function of the extent of epoxide ring reaction *P* for a DGEBA/DDM system at 70 °C; gel point P_{gel} = 0.58

(reprint from [104], with permission from Elsevier Science)

Ultrasound is sensitive to the local concentration of oil in emulsions and thus enables monitoring of creaming and flocculation processes [112], [113]. It is applicable to both dilute and concentrated emulsions.

Ultrasound is not only a tool for monitoring chemical reactions but also one for initiating them. The origin of the enhancement of chemical reactions by ultrasonication is the intensity of the cavitation bubbles produced in the sonicated medium at higher sound intensities [87], [88], [114-116] (see ⟶ Sonochemistry).

The dependence of ultrasonic parameters on grain sizes in heterogeneous media enables one to determine particle sizes and particle size distributions in latices, emulsions, suspensions, etc. even at very high concentrations of the disperse phase [117-121]. Thus, acoustic spectroscopy (as well as electroacoustic spectroscopy [119], [122]) is developing rapidly as an alternative to light-scattering methods for particle size analysis in dense media [123-127].

Ultrasonic microsensors are used for materials characterization and reaction monitoring [81], [83]. Ultrasonic microsensors based on the quartz crystal microbalance (QCM) principle are very sensitive for a wide variety of chemical applications.

The high precision and ease of measurement of the QCM frequency has made it a useful tool for measuring slight changes in mass on the QCM electrode surface. By coating the surface with a sensitive layer, the QCM can be used as selective gas or even under-liquid sensor. The determination of contact angles and surface tensions with a QCM is described in [128]. Detergency processes have been monitored in real-time by using a QCM [129]. The use of shear-horizontal (SH) acoustic plate mode (APM) devices to monitor cross-linking reactions in polymer films in real time is described in [130]. Photo-cross-linking of diacetylene thiol-based monolayers on surface acoustic wave sensors (SAW) has been monitored in situ [131]. Recent developments include the application of fiber-optic interferometric ultrasound sensors for monitoring the cure of epoxy resins [132], [133].

In addition to the active ultrasound measurements discussed above passive ultrasonic measurements can also be utilized to monitor chemical reactions. In active ultrasound, an acoustic wave is generated and changes to the wave caused by the ongoing process are being measured, whereas the acoustic emissions created by the process itself are the signals of interest in a passive ultrasonic measurement [134]. Acoustic emissions have been measured for equipment fault detection, gas – liquid mixing and flow, bubble formation and monitoring, foam break-up, powder flow and mixing, particle collision monitoring in solids and solid – fluid suspensions, compaction, and chemical reaction monitoring. In particular, chemical processes with phase changes during the course of the reaction and processes including granular material are acoustically active.

4. Dielectric Spectroscopy

4.1. Theory and Mechanisms

Dielectric spectroscopy deals with the electrical response of the polarization ***P*** (ω) of matter to the application of an oscillating electric field ***E*** (ω)

$$\boldsymbol{D}(\omega) = \varepsilon_o \boldsymbol{E}(\omega) + \boldsymbol{P}(\omega) = \varepsilon^*(\omega)\varepsilon_0 \boldsymbol{E}(\omega) \tag{25}$$

where ***D*** is the dielectric displacement vector, ω is the angular frequency, and ε* and ε_0 are the dielectric permittivity and the permittivity of free space, respectively. Several atomic and molecular mechanisms contribute to the dielectric behavior of matter [135-138]:

1. Electronic polarization (i.e., induced dipole moment due to the displacement of electrons from their equilibrium position with respect to the nucleus)
2. Displacement polarization (atomic, ionic, lattice polarization; e.g., induced dipole moment due to the deflection of ions from their equilibrium positions in molecules)
3. Orientation polarization of permanent dipoles present in the system (i.e., alignment to the direction of the external field)
4. Motion of intrinsic and extrinsic charge carriers (ions, particles)
5. Charge transfer and polarization at electrodes
6. Interfacial polarization and distortion of the electrical double layers at interfaces in heterogeneous systems

A certain mechanism contributes to the overall polarization of the sample if its characteristic relaxation time is faster than the time scale of the external field. Hence, the various polarization mechanisms can be distinguished on the basis of their different frequency dependencies.

Time scales for resonances of electronic and displacement polarization of atoms and ions are in the femtosecond (10^{-14} to 10^{-15} s; UV region) and picosecond range (10^{-12} to 10^{-13} s; IR region), respectively. Thus, these induced dipoles contribute instantaneously to the dielectric properties of matter typically measured in the frequency range 10^{-5} to 10^{11} Hz.

Key phenomena determining the change of dielectric properties during the course of a chemical reaction are orientation polarization of permanent dipoles, migration of charges, and interfacial effects in heterogeneous systems.

In contrast to electronic and atomic polarization, the orientation of permanent dipoles is time-dependent and not always instantaneous. It is governed by the (micro) viscosity of the immediate surroundings. In polymeric systems, it requires cooperative motion of chains or chain sequences, too. Dipole relaxation is the strongly temperature dependent reorientation of dipoles due to thermal fluctuations after the removal of the external field. As the frequency is scanned, various characteristic dipole relaxations accompanied by corresponding losses are observed.

The migration of charges mainly influences the dielectric losses. The (ionic) conductivity contribution to the loss factor is inversely proportional to the frequency of the external field. Ionic conductivity can be correlated with viscosity, since fluidity is indicated by the ease with which charge carriers can migrate through the sample.

The complex dielectric permittivity ε*(ω) is composed of two parts, a real (or storage) component ε′(ω) in phase, and an imaginary (or loss) component ε″(ω) out of phase with the applied oscillating electric field (Eq. 26).

$$\varepsilon^*(\omega) = \varepsilon'(\omega) + i\varepsilon''(\omega) \tag{26}$$

where *i* is $\sqrt{(-1)}$. ε ′ (ω) is proportional to the capacitance of the sample, and ε″(ω) is influenced both by the material's conductivity and by dipolar losses. A sigmoidal change in ε′(ω) and the appearance of a peak in ε″(ω) is indicative of a relaxation process (Fig. 9)

$$\varepsilon'(\omega) = \varepsilon'_0 - \frac{(\varepsilon'_0 - \varepsilon'_\infty)\omega^2\tau^2}{1+\omega^2\tau^2} \tag{27}$$

$$\varepsilon''(\omega) = \frac{(\varepsilon'_0 - \varepsilon'_\infty)\omega\tau}{1+\omega^2\tau^2} \tag{28}$$

where τ is the relaxation time. The loss factor tan δ is defined by

$$\tan\delta(\omega) = \frac{\varepsilon''(\omega)}{\varepsilon'(\omega)} \tag{29}$$

Figure 9. Dielectric relaxation: Dielectric permittivity and dielectric loss as a function of frequency

As indicated above, the dielectric permittivity is not a constant but a function of frequency. Additionally, ε^* is strongly influenced by temperature since both the transitional mobility of charge carriers as well as the reorientational motion of dipoles are temperature-dependent. For some cases in the absence of chemical reactions, the temperature dependence of dielectric properties can be described in terms of Arrhenius and Williams – Landel – Ferry (Vogel – Fulcher) type relations, depending on the nature of the dipolar motions (single activation and cooperative process, respectively).

In addition to the complex dielectric permittivity, there are several other quantities that can be alternatively derived from dielectric spectra [139], [140]. These include the impedance and admittance (or conductivity), the dielectric modulus, and the susceptibility. Admittance spectra $Y^*(\omega)$, the inverse of impedance spectra $Z^*(\omega) = Z'(\omega) - iZ''(\omega) = (Y^*(\omega))^{-1}$ for linear response, can be calculated from permittivity data according to Equation 30.

$$\varepsilon^*(\omega) = \frac{Y^*(\omega)}{i\omega C_0} \tag{30}$$

where C_0 is the equivalent capacitance of free space.

Transformations from one formalism to another can help resolve particular aspects of the relaxation processes, but no new information can be extracted in the linear response regime of the material. The impedance spectrum $Z^*(\omega)$ is often used for discussion because dielectric data can be analyzed in terms of equivalent electrical circuits consisting of resistors and capacitors connected in parallel and series. The $Z^*(\omega)$ formalism (e.g., Z'' vs. Z' plots) is particularly helpful in separating bulk and surface phenomena (e.g., polarization in the bulk and electrode polarization).

4.2. Instrumentation and Applications

Instrumentation. According to the frequency of the external electric field, several frequency regimes for dielectric experiments can be distinguished which require different measurement principles [140-142] (Fig. 10).

Figure 10. Principles of dielectric measurements: A) Frequency response analysis technique; B) Resonance circuit; C) standing wave in hollow conductor

PS: Power source

The common instrumentation in the *impedance regime* from about 10^{-5} to 10^{8} Hz includes current – voltage measurements in electrode/sample/electrode sandwich arrangements of electrical (ratio-arm) bridges, and resonance (oscillating) circuits. The main techniques for dielectric reaction monitoring are (1) the direct a.c. measurement of amplitude and phase between voltage and current over a certain frequency range by using a frequency response analyzer (FRA), and (2) step voltage application (or removal) with rapid acquisition of the current response over time and transformation of the signal into the frequency domain.

Minimum time intervals for dielectric measurements are on the order of tenths of seconds, so dielectric spectroscopy in the impedance frequency regime is suitable for on-line monitoring of chemical reactions. Typical accuracies of measurements achievable in the impedance frequency regime are about ± 0.05 % for ε', ± 0.2 % for ε'', and better than 10^{-4} for tan δ.

Dielectric cells for liquids are generally simple and consist of two concentric cylinders with the fluid in the space between them. These measurements are of very high precision because of the good dimensional stability of the cells. Solid samples are typically sandwiched between metal plate electrodes as in a capacitor. Compared to liquid cells, solid sample set-ups are quite complicated because they must take into account for the sample's thermal coefficient of expansion.

The *radio regime* from about 10^{6} to 10^{10} Hz requires resonance circuits (low ω) or guided-wave techniques (high ω; e.g.,

standing waves in hollow conductors).

The typical equipment for the *microwave region* from 10^9 to several 10^{11} Hz is coaxial or rectangular waveguides.

Propagating wave techniques are utilized in the *IR and UV – VIS regimes* above a few 10^{11} Hz with Fourier transform technique as the method of choice.

Applications. Chemical reactions are accessible to reaction monitoring by dielectric spectroscopy if they lead to changes in the rate of motion of molecules contributing to the dielectric response of the mixture (e.g., rotational or vibrational motion of dipoles and translational motion of charge carriers).

Many applications of dielectric spectroscopy published so far are for monitoring the cure of resins. Dielectric spectroscopy can detect changes in the polymer cross-link density during the course of polymerization (Fig. 11). When van der Waals or other weak interactions between molecules are replaced by covalent bonds during the conversion of low-viscosity monomers into polymers, the dipole moments of molecules and the mechanisms of their Brownian diffusion change, as does the size of the diffusing moieties. The restrictions on the diffusion of dipoles and charge carriers increase [143-148].

Figure 11. Real and imaginary impedance as a function of time with frequency as parameter during the reaction of the diglycidyl ether of bisphenol F (DGEBF) with 4,4′ methylenedianiline (MDA) at 36 °C [146]

a) Z' = 500 Hz; b) Z'' = 500 Hz; c) Z' = 2000 Hz; d) Z'' = 2000 Hz; e) Z' = 10 000 Hz; f) Z'' = 10 000 Hz

Both the real and the imaginary parts of the dielectric permittivity can have dipolar and ionic-charge polarization components. At lower frequencies, ε'' is typically dominated by the mobility of ions in the sample, whereas dipolar reorientation mobility contributes to ε'' at higher frequencies (Eq. 31).

$$\varepsilon^*(\omega) = \varepsilon^*_{\text{dipolar}} - i\frac{\sigma_{\text{dc}}}{\omega\varepsilon_0} \tag{31}$$

Here σ_{dc} is the d.c. conductivity due to ever-present ionic impurities [149], [150]. The ionic mobility (i.e., σ_{dc}) is a molecular probe for quantitatively monitoring viscosity changes during cure. At short curing times, ε'' is dominated by the d.c. conductivity. When gelation occurs, the d.c. conductivity decreases strongly since the mobility of the charge carriers decreases due to network formation. Peaks in ε'' indicate when dipolar reorientation processes contribute to ε''.

The ionic conductivity signal of dielectric measurement data has been used to study curing of epoxy resins. The conversion was calculated based on a Williams – Landel – Ferry model approach [151]. Dielectric spectroscopy in the 10 to 10^5 Hz frequency range with a ratio-arm bridge has been used to monitor the UV polymerization of a polymer-stabilized liquid crystal cell containing a mixture of nematic and chiral liquid crystals together with DSM monomer and photoinitiator [152]. The authors discuss their results in terms of capacitance units. They have shown that the decreasing loss serves as an excellent monitor for changing molecular processes and the state of photopolymerization, whereas the capacitance itself does not change dramatically during the course of the polymerization. Low-frequency losses observed at the beginning of the reaction are mainly caused by ionic impurities. After polymerization, the liquid crystal cell has the dielectric characteristic of a relatively low loss dielectric.

An electrical impedance spectroscopy method has been developed as a real-time online control tool for thermoset composite manufacturing by exploiting the change of the imaginary impedance maximum as a reaction progress indicator [153].

In particular, dielectric spectroscopy is the method of choice for following the curing of polar coatings. In these thin-layer systems, very high signal-to-noise ratios can be achieved because their capacitance is inversely proportional to their thickness, like the capacitance in a plate capacitor as a function of interplate distance. A special thin-layer dielectric method has been devised which measures the dissipation factor of an adhesive during the cure of adhesively bonded joints and converts it into the degree of cure of the adhesive [154].

Dielectric spectroscopy has been also applied to disperse systems [155-158]. The relaxation pattern is the dielectric fingerprint of a colloidal system [159]. Correlations between relaxation frequencies and suspension properties such as particle volume fraction, electrolyte concentration, Zeta potential, pH, surface conductivity, particle radius, Debye screening length, degree of ionization, and diffusion coefficient have been developed [160], [161]. These characteristics change during reactions in colloidal systems, and on-line monitoring is possible. Moreover, dielectric spectroscopy is especially valuable for studying concentrated and opaque dispersions. For a latex exhibiting a low-frequency relaxation process, the relaxation time at the loss maximum $\tau = 1/\omega_{max}$ is proportional to the square of the particle radius, and inversely proportional to the diffusion coefficient of the electrical double layer of counterions up to 30 % total solids [162].

[Top of Page]

5. Optical Spectroscopy

5.1. Introduction

Optical spectroscopy covers the range of the electromagnetic spectrum from the ultraviolet (UV, $\lambda \gg$ 10 nm) to the

infrared (IR, λ < 1 mm). Experimental equipment for optical spectroscopy in this wavelength range is constructed with typical optical elements such as mirrors, lenses, gratings, and optical filters. The incident energy is delivered by light sources. The long-wavelength end of the electromagnetic spectrum (i.e., millimeter range) requires completely different experimental techniques (e.g., hollow conductors for microwave spectrometry) as does the short-wavelength end ($\lambda \ll$ 100 nm) with special X-ray and γ-ray equipment.

Electronic absorptions determine the spectral features observable in the UV – VIS region. Molecular vibrations, rotations, and combined rotational-vibrational transitions of molecules can be detected in the near (NIR) to the far (FIR) infrared wavelength range. Spectra can either be recorded in absorption (UV, VIS, NIR, IR, FIR) or emission (IR, Raman, fluorescence).

For general reading, fundamentals, instrumentation and applications, see [12] and ⟶ Ultraviolet and Visible Spectroscopy and ⟶ Infrared and Raman Spectroscopy.

5.2. Instrumentation for Reaction Monitoring

Spectroscopy over the entire spectral range of optical wavelengths has been applied to on-line process monitoring for several decades. The vast majority of applications is based on nondispersive instruments, and light absorption or emission is typically measured either at a single wavelength or by integration over a certain (rather small) wavelength range.

In absorption spectroscopy, the light is generated by monochromatic light sources (including lasers) or polychromatic light sources combined with optical filters. Tuning of the wavelength to characteristic absorptions of certain molecules enables one to detect substances and to observe the variation of their concentration as a function of time with high selectivity and sensitivity.

In transmission measurements, the fundamental relation between the incident light intensity I_0, the transmitted light intensity I_l, and the concentration of the analyte c in a cell of optical length l is given by the Lambert – Beer law:

$$\log \frac{I_0(\nu)}{I_l(\nu)} = \log \frac{1}{\tau(\nu)} = A(\nu) = \varepsilon(\nu) cl \qquad (32)$$

where $\varepsilon(\nu)$ is the (decadic) extinction coefficient of the sample at frequency ν, l is the length of the measurement cell, A is the absorbance (extinction), and τ is the transmittance of the sample. Monitoring procedures based on this classical photometric method are still extensively used because of its simplicity, ruggedness, sensitivity, and low cost and maintenance requirements. It works best for well-characterized continuous material streams but is less advantageous for dynamic processes (e.g., some batch operations).

The number of substances that can be detected simultaneously by nondispersive instruments in absorption and emission modes is limited, and detailed molecular information on the species undergoing a reaction is not available. These restrictions can be overcome by parallel installation of several nondispersive instruments operating at different wavelengths, or utilization of dispersive instruments (spectrometers) to exploit the whole spectral information.

With classical dispersive wavelength-scan spectrometers, data collection is time-consuming because such an instrument records the data points of the spectrum consecutively. Therefore, dispersive scanning spectrometers are not suitable for process monitoring.

However, the substitution of point detectors by array detectors in dispersive instruments offers the opportunity to acquire large amounts of spectrally and/or spatially resolved data in extremely short periods of time. Semiconductor array detectors are characterized by high quantum efficiency, wide dynamic range, fast response, low noise, low power requirement, and continuously decreasing costs. Array detectors suffer from either limited resolution or limited bandwidth. However, the two-dimensionality of some types of array detectors in combination with cross-dispersion enables the complete spectrum to be obtained with high resolution. Since the whole spectrum is available with one shot of light on the detector, chemical reaction monitoring on the sub-second timescale is possible. Another advantage of two-dimensional array detectors is the ability to record several spectra simultaneously in different lines of the array thus enabling multiplexing. Fundamentals and applications of array detectors [charge-transfer devices (CCD, CID), photodiode arrays, and photoconductor arrays] in both absorption and emission spectroscopy are reviewed in [163] (see ⟶ Ultraviolet and Visible Spectroscopy – Detectors).

With Fourier transform (FT) spectrometers, the spectral information is first recorded in the time domain as an interferogram and then Fourier transformed into the frequency (wavenumber) domain. The optical throughput of an FT instrument is very high because light of all frequencies is recorded simultaneously. Depending on the spectral resolution and the signal-to-noise ratio required, FT spectrometers are suitable for monitoring very fast chemical processes on the timescale of seconds to minutes. However, they are less rugged than photometers or array-detector instruments because the interferometer is susceptible to vibrations, for instance, in a production-plant environment.

The introduction of fiber optics has been a major step forward in reaction monitoring by optical spectroscopy. Nowadays, most instrument suppliers offer their spectrometers with optional fiber optics. Optical fibers connect the remote instrument with the reactor or process line for on-line monitoring with the following advantages:

- Reduced risk of fire or explosion in production units
- Reduced interaction of the delicate spectrometer with the hostile process environment
- Enhanced accessibility of various measurement points in a process stream or reactor
- Simplified multiplexing

Light may be delivered and collected through separate single fibers or fiber arrays; alternatively, fibers can be arranged in

integrated fiber bundles in which a light source fiber is surrounded by detector fibers, or in which source and detection fibers are randomly distributed within the bundle. A review of the developments in fiber optic applications in molecular spectroscopy is given in [164] (see ⟶ Chemical and Biochemical Sensors). Commonly used fiber types are listed in Table 4.

Table 4. Fiber types and typical optical wavelength range [164]

Fiber type	Approximate optical range
High-purity fused silica	200 – 2000 nm
Plastics	350 – 1100 nm
Glass	350 – 1800 nm
Low-OH fused silica	250 – 2700 nm
Zirconium fluoride	2 – 5.5 µm
Chalcogenide	3 – 11 µm
Silver halides	5 – 20 µm

Recently, the development of fiber-optic chemical sensors (FOCS) based on evanescent wave absorption (EWA) spectroscopy has experienced much progress and improvement. FOCSs can be employed for real-time in situ monitoring by simply immersing them in the mixture and establishing a connection between the fiber, the light source, and the detection system. They offer fast response times on the order of seconds with all the advantages of attenuated total reflection (ATR) spectroscopy, and considerably improved sensitivity.

Figure 12 shows various instrument/probe/process vessel configurations for the application of optical spectroscopy to the monitoring of chemical reactions. Spectra can either be recorded in transmission, reflection, transflection, or attenuated total reflection. Probes can be directly immersed into the reaction mixture, or the spectra can be recorded through windows in the reactor or pipe wall.

Figure 12. Instrument probe process vessel configurations for the application of optical spectroscopy to monitoring chemical reactions

The polarization state of reflected light can be determined in addition to its intensity with spectroscopic ellipsometry methods ranging from UV to IR wavelengths [165]. Spectroscopic ellipsometry is a powerful tool to characterize optical properties of thin films and near-surface regions of bulk materials. It has been applied to study the deposition of material in CVD processes, thermal evaporation or magnetron sputtering [166], [167].

5.3. Applications of Optical Spectroscopy

5.3.1. *UV – VIS Spectroscopy*

UV – VIS spectroscopy is highly sensitive, but the spectra are less informative because they typically consist of a few broad absorption peaks. Therefore, UV – VIS spectroscopic reaction monitoring is less commonly used than other spectroscopic techniques. Typical applications of UV – VIS spectroscopy include photometric gas analysis in transmission gas cells for the detection of sulfur dioxide, nitrogen oxides, chlorine, mercury vapor, toluene, benzene, methane, ethanol, etc. Detection limits are in the order of tens of ppm in air [8].

A major advantage of the UV – VIS spectral region is that water does not absorb considerably in the entire VIS region up to the mid-UV, thus making it attractive for water and wastewater analysis. UV – VIS absorption measurements in aqueous or other fluid process streams are typically performed in transmission or ATR modes. With ATR probes, even highly opaque mixtures and liquid systems containing strongly scattering particulate solids are accessible to process analysis.

In disperse systems, light scattering by particles accounts for much of the attenuation of the incident light. Thus particle size measurement by UV – VIS scattering methods is common practice in colloid laboratories and at production sites.

The general applicability of UV – VIS spectroscopic techniques as well as their advantages compared to engineering process data in order to obtain characteristics of ongoing chemical reactions, to control reactions, to predict product properties, and to determine end points of batch and blending processes has been discussed in conjunction with data handling methods in detail in [168].

The versatility of UV – VIS spectroscopy in process monitoring has been extended by the development of UV array spectrometers [169].

Optical fibers for use in the VIS region are readily available. Transmission of visible light through optical cables is possible

over long distances for remote process monitoring. It has been shown that fiber-optic UV – VIS spectroscopy and chemometric data treatment (window factor analysis) enable one to detect reaction intermediates of an industrially significant process that could not be detected otherwise (e.g., by HPLC) [170]. UV – VIS fiber optics have also been applied to monitor chemical processes in supercritical fluids [171]. In the short-wavelength UV, however, the optical absorption of the fiber core and/or cladding material restricts light throughput. Recently, evanescent-wave fiber optic absorption sensors for use in the UV and VIS regions have been described [172], [173]. UV reflection spectroscopy with a fiber optic accessory has been used to characterize the cure of bis(maleimide) resins [174], [175].

5.3.2. *NIR Spectroscopy*

Absorption bands in the near infrared originate from electronic transitions of the heaviest atoms and from overtones and combinations of fundamental vibrations in the IR. In organic substances, C – H, N – H, and O – H vibrations give rise to dominant absorptions in the near-IR. Therefore, the detection of water was one of the first on-line applications of NIR spectroscopy. However, water interference may also complicate NIR spectroscopy of aqueous samples [176]. NIR-active vibration overtones and combinations are characterized by low molar absorptivities and high scattering efficiencies, and the NIR bands are broad and overlapped.

The peculiarities of NIR spectrometry lead to important consequences in practice:

1. Near IR wavelengths are able to penetrate into and sometimes even through a sample, thus enabling measurements on real world samples in the millimeter or centimeter thickness range. Spectra can be recorded on most types of liquid, solid, powder, or gaseous samples without sample pretreatment. Sample size may vary from tiny bits to large chunks.
2. NIR spectra contain all the spectral information necessary for fingerprinting, albeit buried under broad and strongly overlapped absorption features. In most cases, the spectra cannot be interpreted directly, unlike the individual peaks of IR spectra, and calibrations and chemometric methods have to be exploited for quantitative analysis. This may cause problems in NIR reaction monitoring of batch processes with frequently changing recipes and reaction regimes because of the necessity to provide an extensive training data set for each process [177].

Typical analysis time is on the order of seconds or even shorter, with sensitivities down to tenths of a percent; hence, NIR is an ideal tool for observing fast reactions. Spectra of chemically changing mixtures can be recorded through quartz glass windows mounted in reactors and pipes or by fiber optic immersion probes for diffuse reflectance, ATR, transmission, and transflection measurements. The application of cheap silica fibers allows truly remote sensing with distances up to kilometers between process and spectrometer because of the extremely low attenuation of quartz in the VIS to NIR range.

NIR equipment suitable for reaction monitoring includes both holographic grating/semiconductor array detector instruments and Fourier transform spectrometers. Light-emitting diode (LED) based instruments have no moving parts because each wavelength band is produced by a different diode with precise wavelength tunability and monochromaticity, thus making the instrument rugged to harsh process environments. LED spectrometers are highly sensitive and selective, with fast response and exceptional dynamic range. So far, they have been applied to on-line monitoring of HF and H_2S traces in refineries. However, their high costs are prohibitive for most on-line applications. Acousto-optic tunable filter (AOTF) based instruments have been occasionally used for on-line analysis. Hadamard transform (HT) spectrometers have not been described for NIR on-line applications so far.

Typical problems with NIR measurements are the need to check the calibration of the instrument, since the instrumental response may change after some time [178], and the sensitivity of NIR spectra to the sample temperature, which complicates training procedures. NIR equipment and the application of NIR to reaction monitoring are reviewed in [179-183] (see ⟶ Infrared and Raman Spectroscopy).

NIR spectroscopy has been widely used for the characterization of epoxy curing [184, 185] with conventional fiber optics [186], [187], evanescent wave high-index fiber optic sensors [188], and the NIR ATR technique [189]. Other fiber optic applications include reaction monitoring in explorative organic synthesis [190], real-time analysis of light alkenes in high-pressure reactors at elevated temperatures [191], remote monitoring of styrene emulsion polymerization in the short-wavelength NIR region [192], and determination of octane in refinery processes [193]. A fiber optic coupled AOTF NIR spectrometer has been described for dryer effluent monitoring in a chemical plant [194]. The number of papers describing the utilization of NIR spectroscopy to monitor the progress of polymerization reactions of silanes [195] and vinyl monomers [196-202] is continuously increasing. One of the major advantages of NIR spectroscopy in polymerization monitoring is the capability to extract molecular mass information for reaction control instantaneously that cannot be measured otherwise in a timely manner [203-205]. NIR spectroscopy has been shown to be suitable for on-line detection of reaction completion in a closed-loop hydrogenator in pharmaceutical production [206], for end-point detection in pharmaceutical high-shear granulation processes [207], and in-line monitoring of the moisture content in fluid-bed dryers [208]. Diffuse reflectance NIR spectroscopy has been evaluated as an on-line technique for the monitoring of powder blending [209-211]. Gas-phase real-time monitoring by transmission NIR spectroscopy is described in [212], [213]. NIR spectroscopy has been utilized to measure major components in the production of acetic acid [214]. On-line particle size monitoring based on NIR spectroscopy has been described for pharmaceutical nanoparticles [215], [216] as well as for emulsion polymers [217]. A promising application of remote-sensing NIR spectroscopy is the on-line identification and classification of plastics material [218-220].

Near-infrared spectroscopy is one of the few analytical methods applicable to real-time monitoring of chemical processes in polymer melts during extrusion [221]. Figure 13 shows a ceramic transmission NIR probe with variable optical pathlength that is adapted to a corotating twin-screw extruder and interfaced to an NIR spectrometer via fiber optic cables. On-line NIR spectra, as shown in Figure 14, provide the quantitative composition of a polypropylene/ethylene – vinyl acetate copolymer mixture during blend formation with an accuracy of about 1 %. With the help of ATR (Fig. 15) and diffuse reflectance probes the formation of styrene – maleimide copolymer (Fig. 16), and the filler concentration in molten, opaque polypropylene/chalk powder composites have been monitored. In the latter application, the inhomogeneous

distribution of filler particles may lead to substantially different spectra during the course of extrusion. The scattering contribution of the particles to the NIR spectra has to be corrected before chemometric analysis. Appropriate chemometric calibrations models are required in both cases [222-224]. HANSEN et al. [225-228] were even able to derive rheological properties of ethylene – vinyl acetate copolymers from NIR spectra recorded in-line in an extruder via fiber optics.

5.3.3. *IR Spectroscopy*

Infrared spectroscopy has a long tradition of use in chemistry, materials science, physics, and even reaction monitoring [229]. It is one of the standard techniques in most analytical laboratories. The IR region of the spectrum is highly specific and very sensitive to molecular structures. Individual peaks can be assigned unequivocally to chemical species and calibrated for analyte concentration. The timescale for FTIR spectroscopic analysis is on the order of seconds. All of this makes IR spectroscopy attractive for on-line process monitoring.

High molar absorptivities in the IR are advantageous for gas analysis but may present challenges for liquid analysis because sample layer thicknesses (optical pathlengths) would have to be in the micrometer range to transmit IR radiation. This distance is too short for circulation of the reaction mixture, so transmission and transflection measurements cannot be used for process monitoring.

The technique of choice is ATR spectroscopy. The short penetration depth of the evanescent wave is both the strength and a limitation of ATR spectroscopy. ATR crystals are prone to surface fouling and layer build-up, which leads to interference with the process signals. Additional issues to be considered with respect to on-line applications of ATR are the scratch resistance of the crystal; the relatively low light throughput, which requires sensitive detectors; and the linearity (or nonlinearity) of calibration.

A major obstacle to industrial IR on-line applications is the lack of appropriate fibers transparent to IR radiation. The chalcogenide fibers currently used are very expensive and have only limited light throughput and hence do not enable remote monitoring. Infrared spectrometers should be installed close to the process to allow the use of automated sampling devices, short fibers, or optical systems that transmit the light via mirrors and tubes to the analyzer. The latter option is shown in Figure 5, in which a “mirror-arm” is interfaced to an FTIR spectrometer. In Figure 17, a waterfall spectrum and the corresponding line intensities as a function of time are shown for the reaction of secondary amines with paraformaldehyde. In this case, a linear calibration model makes it possible to examine the reaction kinetics on-line on a quantitative basis.

Figure 17. Waterfall spectrum (a) and the corresponding line intensities (b) as a function of time for the reaction of

secondary amines with paraformaldehyde (courtesy of Mettler-Toledo GmbH, Analytical)

In aqueous systems, the strong water absorption in the IR region may interfere with spectral features of interest for reaction characterization. Nevertheless, on-line monitoring of 2-ethylhexyl acrylate/styrene emulsion copolymerization with an ZnSe ATR fiber optic FTIR device has been demonstrated successfully [230].

Applications of FTIR spectroscopy to polymerization reactions include kinetic studies of laser-induced photopolymerization directly in a spectrometer [231], multiacrylate polymerization studies with a quartz crystal ATR device [232], homo-, co-, and terpolymerization reaction monitoring of acrylates and vinyl acetate [233], [234], and monitoring of carbocationic polymerization with ATR probes [235], [236]. A water-cooled mid-infrared chalcogenide fiber-optic probe with an ZnSe crystal was described for in situ monitoring of an acid-catalyzed esterification reaction in toluene at 110 °C [237]. Cross-linking reactions in various resins have been studied by IR spectroscopy [238-242], and FTIR imaging with focal-plane array detection [243]. The melt crystallization process of isotactic polystyrene was studied by means of in situ FTIR spectroscopy [244].

On-line gas process stream analysis was carried out by piping the gas through a transmission gas cell [245] or by means of photoacoustic gas sensors [246]. Chemical processes in thin films and coatings have been investigated by photoacoustic FTIR spectroscopy [247] and in situ IR ellipsometry [248]. FTIR in situ spectroscopy has been applied to monitor yeast fermentation processes [249], and the homogeneously catalyzed liquid-phase hydrolysis of sucrose [250]. It has been shown that pharmaceutical batch processes can be monitored by FTIR real-time analysis [251]. On-line measured mid-IR spectra in combination with multivariate methods (orthogonal projection approach, principal component analysis, multivariate curve resolution) enable the operator to detect the end point of a chemical analysis [252]. ATR – FTIR in conjunction with multivariate quality-control methods has also been explored to control the manufacturing process of PVC extra-corporal medical disposables [253].

5.3.4. *Raman Spectroscopy*

Fundamentals. Raman spectroscopy combines some of the advantages of (FT)IR and NIR spectroscopy without the limitations associated with these techniques. Nowadays, it is one of the fastest growing areas of analytical chemistry.

Raman spectroscopy produces well-resolved spectra of fundamental vibrations comparable to IR spectroscopy. The interaction probabilities of light with the molecule for the two techniques are quite different. Infrared absorption is favored when a molecule has a permanent dipole which is modulated by the vibration. Raman scattering occurs when the molecule is polarizable, with the polarizability modulated by the vibration. Thus the intensities of IR and Raman bands of the same substance are fundamentally different, and the two methods provide complementary information about the molecule. Some of the bands can even be absent in one or the other spectrum.

The Raman line intensity is directly proportional to the number of corresponding oscillators in the scattering volume and the intensity of the illuminating radiation. Line intensity changes primarily reflect concentration changes within the sample, thus making calibration of the spectra rather simple and straightforward. Raman spectroscopy does not require extensive sample preparation, and Raman spectra can be taken from almost all samples without pretreatment.

The Raman effect is an extremely weak, inelastic scattering process. Typically, only 10^{-6} to 10^{-9} of incident photons undergo Raman scattering, and low-loss optical devices are required for proper recording of spectra. In Raman spectroscopy, there is always a competitive mechanism for light emission present, namely, fluorescence of the sample. In some cases, the quantum yield of fluorescence outweighs the Raman scattering efficiency by several orders of magnitude, and the fluorescence of the sample completely obscures the Raman spectrum. The most convenient way to avoid sample fluorescence is excitation at longer wavelengths. However, as the excitation wavelength increases, the light scattering intensity decreases according to a λ^{-4} power law.

Raman signals of some species are much more sensitive than the corresponding IR absorptions. The ability to measure Raman spectra of symmetrical diatomic molecules (for instance O_2, N_2, H_2, F_2, Cl_2, Br_2, I_2 are not active in IR absorption) opens up opportunities in gas analysis. Raman spectroscopy is sensitive to nonpolar molecular vibrations. Hence, double or triple bonds in monomeric or polymeric molecules are strong Raman scatterers. Vinyl or diene monomers can easily be identified, and their concentrations determined by means of their double bonds. Therefore, Raman spectroscopy is an ideal tool for monitoring the disappearance of monomers during the course of polymerization, and for detecting residual monomers in final products. Metal carbonyls in catalysts and cyanides in plating baths give rise to strong Raman signals due to their triple bonds. Raman spectroscopy can be used to monitor the quality of diamond or diamond-like carbon and to distinguish between isomers [254].

Water, with a strong molecular dipole, has an intense IR absorption, but a very weak Raman response. Thus water obscures IR spectra, whereas Raman scattering is more or less oblivious to the presence of water. Hence, Raman spectroscopy can easily be applied to aqueous solutions, emulsions, latices, and suspensions. Disperse systems scatter light because of refractive index differences between particles and the surrounding continuous phase (e.g., elastic Rayleigh or Mie scattering of latices, emulsions, aerosols). Multiple elastic light scattering reduces severely the scattering

volume from which the light for Raman spectroscopy is collected. Hence, confocal illumination and collection optics are essential for efficient sample excitation and signal detection. Light scattering affects spectral intensities but not band shapes. With confocal optics, interference of both the window material and films built up on window surfaces with the spectrum is much reduced, and spectra can be obtained from samples through colored or opaque sample container walls.

Instruments. Dispersive scanning Raman spectrometers operating in the UV or VIS region are not very suitable for process monitoring because of the time required to record a spectrum. Additionally, the short wavelength excitation may cause severe sample fluorescence. The main advantage of dispersive scanning instruments is the very high resolution achievable by using double or triple monochromators.

As in IR spectroscopy, FT Raman spectrometers are suitable for monitoring even very fast chemical processes on the timescale of seconds. For practical and cost reasons, most instrument manufacturers use the same type of interferometers in their IR and FT Raman spectrometers. Hence, excitation in FT Raman spectroscopy is typically at 1064 nm with Nd:YAG lasers. Therefore, sample fluorescence is very much reduced, but FT Raman spectra of aqueous samples are modified by self-absorption of water in the NIR (i.e., for wavenumbers above 2000 cm^{-1} with excitation at 1064 nm). Pros and cons of FT Raman spectroscopy are reviewed in [255-257].

The application of holographic transmission gratings and semiconductor array detectors (CCD or CID) has led to the rediscovery of dispersive Raman spectrometers. The major advantage of these instruments is they do not contain any moving parts and are thus rugged and compact for on-line applications in chemical plants. However, the insensitivity of a CCD at wavelengths above 1050 nm restricts the wavelength of the incident light. For a CCD-based instrument, excitation of the sample has to be done below 800 nm to obtain the entire spectrum up to 3000 cm^{-1}. Most instruments for reaction monitoring are equipped with recently developed inexpensive and compact NIR solid-state diode lasers operating between 780 and 850 nm, whereby 785 nm or 840 nm are commonly used. A review on diode lasers for Raman spectroscopy is given in [258].

In this wavelength range, low-cost silica optical fibers deliver the laser light to the measurement site and return the signal efficiently for remote monitoring. Holographic filters integrated into the probe head remove the Raman signal generated within the excitation optical fiber and prevent reinjection of elastically scattered laser light into the signal return fiber. Raman spectrometry with fiber-optic sampling is described in [259-262].

For trends in instrumentation and applications, see [263-267].

Applications. Prior to the 1990s, only a few publications deal with Raman reaction monitoring. The validity of the method has been demonstrated for the suspension polymerization of styrene [268] and vinyl chloride [269], the thermal polymerization of styrene [270-272] and methyl methacrylate [272], the solution polymerization of methyl methacrylate [273], the γ-initiated polymerization of diacetylene [274], and the microemulsion polymerization of styrene and methyl methacrylate [275].

The decreasing intensity of the ν(C=C) Raman lines of the monomer during the course of the reaction was monitored as a measure of the extent of conversion to polymer. The positions of the Raman double bond stretching vibration of several monomers are listed in Table 5. Raman spectra recorded during emulsion copolymerization of styrene and butyl acrylate are shown in Figure 18. The ν(C=C) double bond peaks of the two monomers cannot be resolved since the spectral resolution of the instrument was on the same order of magnitude as the difference between their peak maxima (ca. 7 cm^{-1}). The double bond peak disappears almost completely during the reaction. Based on the spectral changes as a result of polymerization, the conversion of the two monomers as a function of time can be calculated with an accuracy of about ± 1 %. The combination of Raman on-line monitoring and automated spectra evaluation enables chemical reactions to be controlled efficiently.

Table 5. Double bond Raman lines

Monomer	$\tilde{\nu}$(C=C), cm^{-1}
Vinyl chloride	1607
Acrylonitrile	1610
Vinyl sulfonate	1619
N-Methylacrylamide	1629
Styrene	1631
Methyl acrylate	1635
2-Ethylhexyl acrylate	1637
Butyl acrylate	1638
Diisopropyl fumarate	1638
Ethyl acrylate	1638
Butadiene	1639
Glycidyl methacrylate	1640
Methyl methacrylate	1641
Allyl methacrylate	1641/1648
Veo Va 9/10*	1646

Vinyl acetate	1648
Vinyl propionate	1648
Crotonic acid	1658

* Vinyl esters of versatic acids.

Figure 18. Raman spectra recorded during emulsion copolymerization of styrene and butyl acrylate. The spectra were recorded with a fiber-based instrument equipped with a CCD detector. Laser excitation at 785 nm with an output power of about 90 mW was performed through a glass window in the reactor wall. The accumulation time for each spectrum was about 15 s. Spectra were recorded at regular intervals of 1 min. Hence, the instrument meets the requirements for an on-line process monitoring system.

Between 1990 and 2005 a wealth of publications appeared on in situ Raman investigations, for instance, of polymerization reactions [276-285], epoxy resin cure [286-288], crystalline-state photoreactions [289], fast high-pressure decomposition reactions [290], hydrolysis of acetic anhydride to acetic acid in a hydrothermal/supercritical water reactor [291], liquid-phase chemistry of aliphatic organic peroxides [292], crystallization of polymer melts [293], a PCl_3 production process [294], petroleum distillate quality in pipelines [295], synthesis and hydrolysis of ethyl acetate [296], the manufacture of titanium dioxide [297], the biotransformation by yeast of glucose to ethanol [298], homogeneous catalysis (Heck reaction) using a solvent band as internal standard to improve quantification [299], and chlorosilane stream composition [300]. Chemical reactions have even been monitored in aerosol particles by means of Raman spectroscopy [301-304]. There is evidence that Raman spectra also contain information on the size of particles undergoing a chemical reaction [305], [306].

Raman spectrometers have been attached to microreactors for reaction monitoring [307]. Multiplexing in a chemical production environment can easily be achieved by Raman systems equipped with fiber optics [308]. The development of low-cost low-resolution spectrometers may open new on-line application opportunities in the future [309].

Micro-Raman spectroscopy has been successfully installed for process and growth monitoring and control of GaN, AlGaN, and AlN [310], and for on-line defect review in IC manufacturing processes [311]. Raman compositional mapping of paper coatings enables one to detect the spatial distribution of pigments, binders, and fillers [312]. Large-spot noncontacting Raman probes have been developed to on-line inspect pharmaceutical formulations and tablets [313].

The study of Raman spectra of adsorbed molecules on surfaces is one of the most promising areas in Raman spectroscopy. Molecules adsorbed on metal surfaces show enhancement of the scattering efficiency by up to seven orders of magnitude [314], [315]. This surface-enhanced Raman scattering (SERS) is ultrasensitive for detecting numerous adsorbed compounds by means of their vibrational spectra. Originally, SERS experiments were carried out with either bare metal surfaces or metal colloids mixed with solutions of the sample. Covering the substrates with extremely thin modifying layers enables the construction of chemical sensors for remote monitoring [316-319].

A nonlinear Raman technique, stimulated Raman scattering (SRS), has been used to monitor the bulk polymerization of styrene and methyl methacrylate [320]. In contrast to spontaneous Raman scattering, most compounds show only a few Stokes lines in their SRS spectrum. As a result, spectral interference of SRS-active compounds in a reaction mixture is minimized.

5.3.5. *Fluorescence*

Fluorescence spectral signals are quite intense because of the efficient electronic excitation and fluorescent emission process. This enables measurements down to the nanosecond timescale on small samples with remarkable accuracy. The sensitivity is high over a wide concentration range. The spectral features are rather broad compared to those of other spectroscopic methods. Fluorescent techniques provide information on molecular arrangement and dynamics of micro-heterogeneous systems, and on micropolarity or microviscosity [321], [322].

Steady-state fluorescence spectroscopy and fluorescence lifetime measurements have been used for on-line reaction monitoring. Sources of fluorescence can be the reaction components themselves or a fluorescent probe that is added to enhance the selectivity of the measurement. Reaction monitoring with fiber-optic fluorescence sensors coated with fluorescent probe molecules is an emerging technology. In contrast, fluorescence signals in Raman spectroscopy are a source of disturbance because they originate from largely unknown impurities and mask the more specific Raman signal. The fluorescence technique is potentially much cheaper than Raman spectroscopy.

Fluorescence methods have been demonstrated to be useful in academic research for in situ monitoring of photoinitiated processes [323], curing [324-327] and polymerization [328-334]. Polymer colloids have been characterized by fluorescence quenching techniques in order to draw conclusions about the internal particle structure, transport phenomena, and particle flocculation of latices [335], [336]. A traditional field for the application of various fluorescence techniques are micellization behavior, molecular interactions, aggregation and clouding phenomena in surfactant solutions [337-340]. Optical fluorescence microscopy is capable of in situ chemical analysis of phase-separating polymer blends [341]. Various aspects of latex coalescence and film formation were studied by fluorescence techniques [342-345]. Various monitoring applications of fluorescence-based sensors and fluorescent probes are described in [346-351].

Fluorescence is not commonly used for on-line monitoring of chemical processes outside academia. Nevertheless, fuel in the cylinder wall oil film of a combustion engine has been detected in situ with a fiber-optic laser-induced fluorescence system [352]. Laboratory analytical work published in the past indicates that fluorescence methods may become especially useful to monitor biotechnological processes in the future.

5.3.6. *Other Spectroscopic Techniques*

In addition to the classical optical spectroscopic techniques discussed above laser-based spectroscopic methods are gaining increasing importance for process monitoring, gas analysis and trace element detection. Laser remote sensing techniques have been reviewed in [353].

In a laser gas sensor, the frequency of a tunable laser (diode) or a quantum cascade laser is adjusted to the absorption frequency of a specified gas component thus enabling the detection of molecules from the percent down to the ppm range in a rather complex matrix [354].

A high-energy laser pulse generates a plasma (a dielectric breakdown) on the material of interest in laser-induced breakdown spectroscopy, LIBS (or laser-induced plasma spectroscopy, LIPS). The resulting light emission can be analyzed with a spectrograph [355] to detect gaseous components in air [356], to determine the concentration and size of particles in water [357], to analyze steel components in the melt at elevated temperatures [358], and to identify plastics in a recycling stream [359].

In cavity ring-down spectroscopy (CRDS) a laser pulse is trapped in an optical cavity between two reflecting mirrors. The light intensity within the cavity decays as a function of time [360]. Absorbing species inside the cavity increase the total cavity losses thus enabling the detection of trace molecules in gases.

With the development of multivariate techniques, 3D spectral image analysis became very important for systems where spatial distribution of components is key to process monitoring, understanding, and control [361]. Applications include optical spectroscopic imaging from the UV to the IR wavelength range in absorption, fluorescence and Raman spectroscopy as well as magnetic resonance, X-ray fluorescence or XPS imaging.

[Top of Page]

6. Particle Size Analysis

An important characteristic of disperse systems (latices, emulsions, aerosols, suspensions, powders) is their particle size distribution. Particle sizes affect almost all properties of a disperse system (electrical, optical, rheological, etc.), as well as its stability. The evolution of the particle size distribution is a sensitive indicator of the progress of heterophase reactions, and it determines the application properties of final reaction products.

In this chapter, the main focus is on process particle size measurements in suspensions. For reviews of particle measurements, including in-process particle size distribution measurements and classification of microsized particles, see ⟶ Air – Measurement of Particles and ⟶ Particle Size Analysis and Characterization of a Classification Process.

6.1. Scattering Techniques

The scattering of electromagnetic waves (light, X-rays) and neutrons by particulate matter is a powerful tool for studying particle sizes and shapes, internal particle morphologies, particle dynamics (even under shear), the structure and dynamics of concentrated disperse systems, and particle charges. Wave interference yields information on particle sizes and shapes whenever the wavelength is of a comparable order of magnitude to the size of the scatterer.

Neutron and X-ray scattering both rely on the availability of corresponding neutron and radiation sources. Hence, their use for on-line size monitoring is extremely limited.

Particle size determination by light scattering techniques is a well established broad field of experimental methods. In addition to inelastically scattered light (Raman and Brillouin scattering), there are two basic approaches that exploit light scattering data for on-line particle size analysis: Static light scattering (SLS) and dynamic light scattering (DLS). SLS methods involve measurement of the time-averaged angular scattering as well as turbidity measurements (i.e., elastically scattered light). DLS measures the very small frequency shift of scattered light caused by translation and rotation of scatterers, or, in the FT time domain, fluctuations of the light intensity by correlation techniques. Thus, quasi-elastic light scattering (QELS), Rayleigh linewidth/spectroscopy, intensity correlation spectroscopy, and photon correlation spectroscopy (PCS) are synonymous with DLS.

Most of the light scattering techniques require extensive dilution of the extracted sample to avoid multiple-scattering effects. Automatic dilution devices are interfaced to the light scattering instrument for on-line applications. Direct optical access to the (undiluted) reaction mixture became possible with the development of fiber-optic probes and instruments.

For general reading see [362-364].

6.1.1. *Turbidimetry*

The turbidimetric experiment is rapid, precise, reproducible, and absolute (i.e., no calibration is required). Spectrophotometers are readily available. Turbidity gives a measure of the attenuation of light traversing a suspension or aerosol of nonabsorbing particles. Turbidimetry may require dilution of the mixture to avoid multiple scattering effects. The wavelength-dependent turbidity τ of a (diluted) sample provides information on particle size and concentration. Turbidimetric (and nephelometric) measurements at single wavelengths can be used to determine the concentration of particulate matter in liquid and gaseous process streams. Fraunhofer diffraction is used for particles sizes $\gg$ 1 µm.

Several publications describe the determination of particle size during emulsion polymerization by specific turbidity τ/φ or turbidity ratio measurements [365-367]. For a polydisperse suspension, the turbidity is related to the polymer volume fraction φ according to

$$\tau = \frac{3}{2}\varphi \frac{\int_0^\infty d_p^2 \cdot K\left(\frac{d_p}{\lambda_m}, \frac{n_p}{n_m}\right) f(d_p) \mathrm{d}d_p}{\int_0^\infty d_p^3 f(d_p) \mathrm{d}d_p} \tag{33}$$

where K, f, λ_m, and d_p are the scattering coefficient, the size distribution function, the wavelength of light in the medium, and the particle diameter, respectively. The quantities K and τ are functions of both the refractive indices of the particles n_p and of the medium n_m, and of the size of particles relative to the wavelength of the light d_p/λ_m. K can be calculated from the general Mie theory. If the size distribution function f is known, the particle size distribution can be estimated from specific turbidity measurements at several wavelengths. Despite the complicated dependence of τ on K and its direct dependence on the distributional form f (which is sometimes unknown), the specific turbidity can yield (1) the turbidity average particle diameter and the volume-surface average (i.e., $D_{3,2}$) diameter for small and large particles, respectively, for any value of $m = n_p/n_m$, (2) the weight average diameter for $m < 1.15$ and particles that are smaller than the wavelength of the light, and (3) an estimate of the weight average particle diameter in all other (monomodal) cases if a log-normal particle size distribution is assumed [366], [367].

Turbidimetry has been used to study the coagulation kinetics of aqueous dispersions [368], [369]. Efforts were made to extend the theoretical basis of turbidity to higher concentrations [370-372].

6.1.2. *Angular Static Light Scattering*

Angle-dependent static light scattering measurements with goniometers are not very suitable for on-line monitoring because of the time required and the demands discussed in ⟶ Plastics, Analysis – Light Scattering. A fast-response multichannel photometer capable of on-line monitoring even at moderate concentrations is described in [373]. The scattered light is simultaneously measured at 168 angles. This static light scattering instrument has a response time of 100 ms and an angular resolution of 1°.

Static light scattering at a fixed angle is valuable for studying the formation and aggregation of latex particles during emulsion polymerizations [374].

Several instruments are on the market which automatically dilute aqueous dispersions to a desired (extremely low) concentration and perform static multiple-angle light scattering. Different modes of light scattering (including Fraunhofer diffraction) are typically combined within one instrument to enable particle size analysis over a wide range of sizes.

6.1.3. *Dynamic Light Scattering*

Particles suspended in a continuous medium undergo random Brownian motion. Hence, the phase of light waves scattered by Brownian particles also fluctuates randomly in a time-resolved light scattering experiment. Their mutual interference leads to a net randomly fluctuating scattered light intensity $I(t)$ at the detector. The normalized autocorrelation function $g_2(t')$ of the light intensity as a function of time delay t' is given by

$$g_2(t') = \frac{\langle I(t) \cdot I(t+t') \rangle}{\langle I \rangle^2} \tag{34}$$

with $\langle I(t) \cdot I(t+t') \rangle$ ($t' \longrightarrow \infty$) = $\langle I \rangle^2$, the square of the average scattered light intensity. The field autocorrelation function $g_1(t')$ can be calculated if the Siegert relation holds

$$g_2(t') = A + B \cdot \left| g_1(t') \right|^2 \tag{35}$$

where A and B are instrument-related constants.

For a monodisperse system of Brownian particles, their diffusion coefficient D can simply be derived from $g_1(t')$ according to Equation 36

$$g_1(t') = \exp\left(-q^2 D t'\right) = \exp\left(-\Gamma t'\right) \tag{36}$$

where Γ is the decay constant. The scattering vector q is defined as

$$q = \frac{4\pi n}{\lambda} \sin\left(\frac{\theta}{2}\right) \tag{37}$$

where n, λ, and θ are the refractive index, the wavelength of light, and the scattering angle, respectively. The Stokes – Einstein equation relates the diffusion coefficient D to the hydrodynamic radius of the particles r_h

$$r_h = \frac{k_b T}{6\pi\eta D} \tag{38}$$

where k_b, T, and η are the Boltzmann constant, temperature, and viscosity of the dispersion medium, respectively.

For polydisperse systems, the autocorrelation function becomes a sum of exponentials with a distribution function $G(\Gamma)$

$$g_1(t') = \int_0^\infty G(\Gamma) \exp(-\Gamma t') d\Gamma \quad (39)$$

Particle size characteristics and distribution functions can be derived from measured autocorrelation functions by (1) directly inverting the Laplace integral equation (Eq. 39, a mathematically ill-conditioned problem), or (2) parameter fits, exponential sampling, regularization techniques, and histogram analysis.

Some advantages make dynamic light scattering attractive for on-line applications:

1. DLS is an absolute method; no calibration over time is necessary. With conventional DLS systems, accuracies of ± 1 % for the mean particle diameter can be achieved on a routine basis within a few minutes of measurement time. Care must be taken in reacting systems, where either temperature or viscosity change during the course of the reaction (see Eq. 38).
2. Particle properties such as density or refractive index do not affect the time behavior of the intensity fluctuations. Thus, the derived particle sizes are independent of the chemical composition of the particles.
3. In the single-scattering regime, diffusion coefficients and particles sizes are independent of particle concentration. This is an advantage over turbidity measurements, for which exact knowledge of the particle concentration is crucial for size calculations.
4. The use of inexpensive fiber-optics allows remote monitoring.

Two approaches are possible for on-line DLS measurements:

1. A device interfaced with the process line or reactor automatically captures a certain amount of the mixture and dilutes it sufficiently to avoid multiple scattering and allow noise-free measurements [375].
2. A fiber-optic probe (optode) is directly immersed into the mixture and both illuminates the colloidal system and collects the scattered light (FOQELS: fiber optic quasi elastic light scattering; FODLS: fiber optic dynamic light scattering [376-378]. This backscattering arrangement shortens the light path within the dispersion and makes the method applicable to turbid and concentrated systems. Monomode fibers further suppress multiple scattering effects [379].

Particle growth during emulsion polymerization has been studied by conventional DLS [380-384] and fiber-optic DLS [385], [386].

6.1.4. *Other Optical Techniques*

The effect of multiple scattering can be useful for studying highly concentrated dispersions. The path of multiply scattered light in the dispersion is similar to the path of particles or molecules under the influence of Brownian diffusion [387-390]. The concept of photon migration or diffusing wave spectroscopy (DWS) has already been applied to particle size determination.

Colloidal refractometry is an optical method that measures the refractive index *n* of a dispersion and analyzes it by using Mie theory. This method allows the structure of concentrated dispersions to be probed in the undiluted state. The measured values of *n* can provide a measure of the volume average particle size [391].

Frequency-domain photon migration has been employed to on-line monitor the variation of the active pharmaceutical ingredient concentration as well as changes of particle sizes in powders [392]. Chord length distributions of particles in the micron to millimeter range of emulsions and suspensions can be on-line determined by means of focal-beam reflectance measurement methods [393], [394]. Particle sizes ranging from 50 nm up to 3 μm are accessible by means of dynamic extinction spectroscopy [395]. Transmission fluctuation spectrometry [396], [397] combined with the autocorrelation technique covers a particle size range from 1 μm to 1 mm and a particle concentration of up to 12 % of flowing particle suspensions [398].

6.2. Separation Techniques

Recently, particle separation techniques (chromatography, fractionation) have been developed that are capable of on-line monitoring of particle size. These methods require fully automated removal of samples from the reaction mixture, dilution, and injection into the instrument.

Size exclusion chromatography (SEC) is applicable with porous (liquid exclusion chromatography LEC) and nonporous packing of the column (hydrodynamic chromatography HDC). Particles are separated because of the dependence of the rate of particle flow through gaps between packing beads on particle size. Larger particles are eluted first since they travel through larger gaps with higher flow rates. The main advantage of SEC methods is that particle size distributions can be obtained directly without any assumption regarding the mathematical form of the distribution. Calibration of the instruments with particle size standards is necessary but simple. Disadvantages are the limited resolution because of radial dispersion, and relatively long elution times of up to half an hour [399], [400].

Much higher resolution than with SEC methods can be achieved by capillary hydrodynamic fractionation (CHDF) [401] and field-flow fractionation (FFF). The fluid in a CHDF capillary has a parabolic velocity profile with the greatest fluid velocity at the center of the tube and zero velocity at the wall. Particles move radially due to their Brownian motion. Larger particles are unable to approach the wall as closely as smaller particles. Hence, larger particles travel through the tube faster than smaller particles. This separation effect is exclusively a function of particle size; it is independent of particle density. The efficiency of capillaries for separating particles depends on the eluent viscosity, the flow rate, and the capillary diameter. The optimum particle size for CHDF analysis is < 1 μm. The main disadvantage of this method is the possibility of capillary

clogging. The CHDF method has been used to monitor the evolution of the particle size distribution during emulsion [402] and miniemulsion polymerization [403].

Field-flow fractionation (FFF) is a family of chromatography-like elution techniques based on influencing the rate of particle flow through a narrow channel by applying an external field perpendicular to the flow direction [404-408]. The external field separates particles of different sizes by driving them into different localized laminas (< 10 µm thick) of the parabolic velocity profile of the eluent within the fractionation channel thus causing their separation. In contrast to CHDF, FFF does not necessarily require calibration of the instrument. Retention times for particles of different sizes can be calculated directly from first principles.

FFF can be classified according to the type of applied field into sedimentation, thermal, electrical, cross-flow, and steric. The most suitable external fields for particle size analysis are cross-flow and sedimentation fields. The particle separation in cross-flow occurs according to the hydrodynamic radius of the particles, whereas their effective weight separates particles in a sedimentation field. The particle size ranges for cross-flow and sedimentation field FFF are 10 nm to 100 µm and 50 nm to 100 µm, respectively. Recently, FFF (including thermal FFF) has been used to characterize the size and composition of core/shell latices [409]. On-line coupling of FFF with multi-angle laser light scattering is described in [410], [411].

7. Chromatography

7.1. Introduction

Chromatographic methods (especially gas chromatography) are the most widely applied family of techniques for determining the chemical composition of reaction mixtures. For a discussion of basic principles, techniques, instrumentation, sample extraction and preparation, applications (including on-line applications), advantages and limitations see ⟶ Basic Principles of Chromatography, ⟶ Gas Chromatography, and ⟶ Liquid Chromatography.

A comprehensive discussion of (gas) chromatography for on-line monitoring of chemical reactions has been published [412]. Process applications can also be found in [413-416].

The term “process chromatography” almost exclusively refers to the application of gas chromatography (GC) to monitor chemical reactions or process streams. Advantages of GC are its simplicity, high sensitivity and selectivity, and ease of automation. Liquid chromatography (LC, including HPLC), supercritical fluid chromatography (SFC), electrophoresis (EP), and ion chromatography (IC) are less common in process monitoring because of their higher maintenance requirements, greater complexity, and higher costs for purchase and maintenance.

Because GC (like other chromatographic methods) is an inherently discontinuous *batchlike* analytical technique which is applied to *continuously* monitor a chemical system in a nonbenign environment, there are distinct differences between laboratory and process instruments, although the basic components of a gas chromatograph can be found in instruments of both categories (Fig. 19) and the basic principles of separation are the same.

Figure 19. Schematic of a process GC analyzer GS: gas supply for carrier, auxiliary, and purge gases; V: valves for preseparation, column switching, and injection; VP/LP: vapor-phase/liquid-phase sampling; SHC: sample handling and conditioning system; R: reactor; S: separation unit; C: column(s); D: detector; O: thermostatically controlled oven; PC/C/NW: personal computer/controller/network; W: waste gases

In contrast to laboratory instruments, process analyzers have to meet stringent safety and explosion-proof requirements because of their close vicinity to the product line. The typical GC process instrument is designed to detect and monitor only one or a few (previously known) components of the reaction mixture so as to control a chemical reaction or process stream. This requires special injection valves and column-switching devices. As in conventional GC, the amount of sample required for process GC is extremely small. Hence, the sampling system must ensure that the sample is representative of the process to be monitored. Often, a sample conditioning system is necessary to further process the sample, which may still be reactive, for GC analysis.

The nonspecific character of detection based exclusively on retention time (i.e., no positive identification) makes GC preferably suitable for process monitoring of continuous processes with small variations in composition. Different molecules may have the same retention time, confusing quantification of the chromatograms and leading to misinterpretation of overlapping peaks. Additionally, GC analysis requires time for separation and detection. This time interval must be reasonably short compared to both the run time of the reaction and the time required to feed the analytical result into a process controller, and to influence the reaction.

7.2. GC Hardware Components

Carrier Gas. In principle, the same carrier and auxiliary gases can be used in both laboratory and process GC analyzers (usually hydrogen, helium, argon, synthetic air, or nitrogen, depending on the application). Most high-purity gases are supplied in containers (e.g., high-pressure gas cylinders). For an on-line operation of the GC analyzer, the gas storage and delivery systems should be equipped with valves that switch automatically between empty and full containers.

Sampling. The quality of a GC analysis of a reacting mixture is only as good as the quality of the samples withdrawn from it. Because of the very small amounts of sample necessary for GC, it is crucial to withdraw samples that are representative

of the mixture. The sampling point (sample probe) should be located at a point in the bulk of the medium where it is homogeneous and well mixed so as to obtain the “true” bulk composition of the mixture. Close to the walls, adsorption and deposition phenomena and stagnant flow may locally change the overall composition.

From an analytical point of view, the best location for the analyzer would be right next to the process line or sampling loop. However, a number of factors and restrictions have to be taken into consideration for placing the chromatograph relative to the sampling point, e.g., 1) space available for installation, 2) maintenance requirements, 3) safety requirements, 4) accessability of sampling point and chromatograph, 5) connection to utilities and supplies (carrier gas, electricity, compressed air), 6) optimization of instrument lag time versus control cycle time, 7) minimization of sample transport, 8) reactivity/stability of the analyte. In most applications, a sample transfer line bridges the distance between sampling point and analyzer. Length and diameter of the transfer line must be optimized for (high) analyte flow. Pressure drop and temperature changes along the line must be controlled. When the analysis is complete, the sample is returned to the process by a separate line or disposed of along with the carrier/purge gas.

In many processes, GC samples are taken at elevated temperature and/or pressure. These samples may contain unconverted components, other reactive ingredients, water vapor, liquids, or solid impurities. Hence, process samples must be appropriately conditioned before feeding them into the GC analyzer. The sample conditioning system performs depressurizing and temperature reduction as well as filtration and removal of liquids (e.g., by vaporization). Its different elements may be close to the sample point (pressure reducer, filter) or close to the analyzer (temperature control, flow control). The conditioning system ensures that the temperature of gaseous samples is held above the dew point to avoid condensation and that the temperature of liquid samples is well below the boiling point to avoid bubble formation in the line.

Sample transfer and conditioning are the most time-consuming part of an on-line GC analysis. The lag time between process and analysis is on the order of a few minutes and must be taken into account in designing reaction control systems based on conventional GC. With microsensor GC systems, timescales on the order of (milli) seconds for on-line analysis are possible.

Analyzer Oven. In contrast to most laboratory instruments, the actual process chromatograph (i.e., injection system and valves, column(s), detector(s), controls) is placed in a single temperature-controlled oven. Temperature control of better than ± 0.05 K suppresses fluctuations in temperature-sensitive processes such as gas flow, mobile-phase diffusion, adsorption/desorption, and chemical interactions. Since detection is solely based on retention time, all processes that can influence retention times must proceed unaltered to avoid loss of calibration under automated operating conditions. Constant temperature is usually guaranteed by circulating heated air within the process analyzer oven or by using high-mass metal heat reservoirs. In some applications, tighter temperature control can be circumvented by an independent delayed injection of a standard or by adding an internal standard to the carrier gas.

Pressure control and programming is dominant in process chromatographs, although some temperature programmable analyzers and gradient systems have been recently described in the literature.

Valves and Columns. In contrast to laboratory instruments, a process chromatograph is usually designed to monitor only one or just a few components of the reacting system for control purposes. Exceptions include some petrochemical applications, in which up to several hundreds of components are monitored simultaneously. Additionally, the process GC analyzer must operate unattended in a rather harsh environment over extended periods of time, but still provide reproducible and stable data. Of special importance is a constant sample volume/mass for injection (and volume of standard, if necessary). Therefore, dedicated valve systems for sample injection and column switching have been developed [412] (see ⟶ Liquid Chromatography – Sample Valve Injectors, ⟶ Liquid Chromatography – Coupling Techniques). For gaseous samples, the sample size is normally defined by the volume of an external sampling loop connected to different valve ports. The injection volume of liquid samples can be defined by the size of internal grooves within the valve or by external sampling loops.

Sliding, rotary, and diaphragm valves with a wide variety of internal pathways and port configurations are commonly used in process chromatography of gaseous samples. For liquid samples, piston (syringe) valves may also be applied. Valves are heated externally or internally. Depending on the component(s) of interest within the complex reaction mixture, cutting (mainly heart-cut technique) and other column-switching techniques (e.g., backflushing) or multicolumn analysis are often combined with precolumn separation (see ⟶ Liquid Chromatography – Column Switching). The main reason for using column-switching techniques in on-line process GC is to drastically reduce the total analysis time and to fully separate the components of interest from the mixture. In general, the same types of valves are used for injection and column switching.

Traditionally, the use of packed columns predominates in process GC. As in laboratory GC, packed columns are being replaced by capillaries in an increasing number of on-line applications. With capillary columns, chromatographic separation is improved, resolution is higher, and analysis time is shorter than with packed columns because of the much simpler flow and diffusion pattern of the analyte. However, capillaries are normally less sensitive, more expensive, and not so easy to use as packed columns. A major drawback of capillary columns in process applications is their sensitivity to flow, pressure, and especially temperature fluctuations.

Columns, their supports, coatings, and packing materials have to withstand possible corrosive action of ingredients of the reaction gas mixture and should be inert to reactions with solute molecules (e.g., by silylation of the column packing material or capillary coatings). The presence of water vapor and oxygen traces in process gases may also be of relevance to column selection.

Detectors in process chromatographs have to comply with the overall safety, robustness, and reliability standards of an on-line instrument. The overwhelming majority of GC detectors utilized in process analyzers are of the thermal conductivity (TCD) and flame ionization (FID) types because of their ease of use and sensitivity to the process components of interest. TCDs are sensitive to changes in the bulk thermal conductivity of the carrier gas in the presence of the analyte, which

gives a concentration-dependent signal, whereas FIDs sense the number of certain ionized molecules entering the flame with a specific flow rate. In some rare cases, photoionization (PID) and flame photometric (FPD) detectors are applied.

Several methods have been utilized in process GC to convert detector output signals (peak areas) into desired analyte concentration values, such as the separate injection of calibration standards, the use of internal standards, and calculations based on relative response for the different detector types.

The basic operations of a GC can also be miniaturized and micromachined on a silicon wafer. Micro-GC devices are compact, more robust, and faster than classical GCs what makes them very attractive for process monitoring applications [417].

7.3. Applications of Gas Chromatography

GC has a long tradition of use for controlling processes and process streams in industry. On-line GC is one of the most important techniques for monitoring distillation, rectification, and conversion processes in refineries and chemical and pharmaceutical plants. It is extensively applied in catalysis research, development, and production to evaluate catalysts and study reaction mechanisms and kinetics. Another field of use is in metallurgical smelters for gas and sulfur analysis in metals. It is widely utilized as a part of workplace safety systems, e.g., to ensure air quality in production units, pilot plants, and laboratories.

On-line GC has proved useful for determining organic substances in water [418], [419], wastewater analysis [420], and air monitoring [421-423]. Reports have been published on the on-line analysis of petroleum [424], [425] and gasoline [426-428], the determination of octane numbers with *n*-alkanes as reference [429], the on-line monitoring of methyl formate conversion to methanol and carbon monoxide [430], Fischer – Tropsch synthesis [431] and thermolysis/decomposition of organic compounds [432], [433]. The application of gas chromatography (among other techniques) for on-line monitoring of polymerization reactions is reviewed in [434]. Gas chromatography of the reaction mixture [435], [436] and the head space of the reactor [437], [438] can be applied for on-line determination of residual monomer composition in emulsion polymerization.

Head-space GC in liquid reaction mixtures is not straightforward for direct reaction monitoring because it requires knowledge of the partitioning of each component between the gas phase above the reaction mixture and the liquid mixture, and, especially in multiphase reactions, between the different phases of the reaction mixture (e.g., aqueous phase, monomer droplets, and polymer particles in an emulsion polymerization). Additionally, the head space should be in thermodynamical equilibrium with the fluid reaction mixture.

The utilization of (mass) sensors for gas and liquid analysis has been reviewed in [439-441], In-line applications of chemical sensors to monitor polymerization reactions has not been described in the literature so far. Such sensors should have a very high selectivity so as to detect components well below the percent range in a matrix of solvent or solvent vapor (including water) containing a large number of ingredients, some of them with a chemical structure comparable to that of the analyte. Additionally, the sensors would have to deal with precipitates on their surfaces.

7.4. Other Chromatographic Techniques

Applications of liquid chromatographic systems to monitoring chemical and biochemical processes are described in [442-448]. SAW sensors are useful gas sensing tools for on-line monitoring of the mobile phase of process HPLC with changing mobile phase composition or gradients [449]. On-line ion chromatography has been used to monitor adipic acid production [450], trace metal ions [451] and cations [452], and oxides in flue gases [453]. Reviews on process ion chromatography can be found in [454] and [455]. In some rare cases, capillary electrophoresis [456], [457] and supercritical fluid chromatography [458], [459] have been described as on-line reaction monitoring techniques.

[Top of Page]

8. Electroanalytical Methods

8.1. Introduction

Electroanalytical methods are based on the interaction of electrical fields with chemical processes or on chemically induced electrical signals on electrodes. The major advantage of electroanalytical methods is the electrical output of the measurement (i.e., electrical current, potential, resistance, or charge), which can directly be processed electronically without any further transformation, in contrast to other monitoring techniques. Although the main application for electroanalytical techniques is process monitoring in aqueous solutions, they can also be applied to nonaqueous and nonliquid systems.

In most electroanalytical measurement systems, the sensing electrodes are in direct contact with the reaction medium and all of its components, not only with the species of interest. This can lead to cross-sensitivity and poisoning, and to abrasion, deactivation, and contamination of the active electrode surfaces. Additionally, the analytical information of interest must be extracted from the integral signal. Calibration of the sensing system is typically necessary at the beginning of a measurement cycle and subsequently in regular intervals. Accumulation of static electricity within the sensing system and on its body must be avoided.

Compact titration configurations for on-line process analytics are commercially available not only for electroanalytical applications such as acid – base titrations but also for precipitation and complexometric titrations [460].

8.2. Conductometry

Conductometric measurements rely on the existence of charges in the medium that are mobile in an applied electrical field (e.g., ions in electrolyte solutions or melts, electrons in metals). In conductometry, no reaction takes place at the

electrodes. Electrical conductance of the medium or electrical capacitance of a measurement cell is the measured quantity. Conductometry in solutions and melts is a nonspecific method because all anions and cations contribute to the medium's conductivity. However, the method is very robust, precise, sensitive, fast, and does not require extensive maintenance.

Concentration c_i and μ_i of all the ions *i* present in a medium determine its conductivity Λ (and conductance *G*)

$$\Lambda = kG = kF\sum_i c_i n_i \mu_i \tag{40}$$

where n_i is the ion valency, *F* is Faraday's constant, and *k* a cell constant. This linear relationship between concentration and conductivity is the basis for concentration measurements in the lower concentration range ($\leq 0.1\ \Omega^{-1}\ cm^{-1}$). For higher electrolyte concentrations, Equation 40 becomes nonlinear because of ionic interactions. Additionally, polarization effects may occur at the electrodes. The temperature dependence of the ionic mobility μ leads to an almost (quasi) linear dependence of Λ on temperature in the temperature range common for conductivity measurements in electrolyte solutions (0 – 100 °C).

Two different principles of conductivity measurements are in industrial use: 1) two- or four-electrode conductive cells with direct electrode contact to the medium, and 2) inductive, electrodeless, and contactless devices.

Contact electrode cells are applied in nonaggressive media. The cell itself is typically part of a Wheatstone bridge operating with low-frequency alternating current to avoid electrode polarization. Two-electrode cells are in use in the conductance range 10^{-8} to $10^{-1}\ \Omega^{-1}\ cm^{-1}$, whereas four-electrode cells are suitable for the higher conductance range of 10^{-3} to $10\ \Omega^{-1}\ cm^{-1}$.

Electrodeless inductive measurements are the method of choice for highly conductive systems; for aggressive, abrasive, or corrosive media; and for high-temperature applications. The medium to be measured is circulated through a loop; two transformer coils are attached to the inert wall material of the loop pipe (Fig. 20). A generator supplies alternating voltage to the primary coil. The induced alternating voltage at the secondary coil depends on the conductivity of the solution circulating through the loop. For contactless measurements, the medium's conductance is typically much higher than $10^{-1}\ \Omega^{-1}\ cm^{-1}$. Inductive devices are less sensitive than electrode cells.

Figure 20. Schematic of an electrodeless conductivity measurement device G: generator; D: detector; P: primary coil; S: secondary coil; ≈: alternating current

The electrical conductivity Λ_d of a disperse system is a function of both the volume fraction of the disperse phase φ ($\varphi \ll 1$) and the electrical double layer properties of the particles (surface conductivity Λ_s, Zeta potential ζ)

$$\Lambda_d = \frac{1}{f}\Lambda_0 + \Lambda_S \tag{41}$$

where Λ_0 is the conductivity of the dispersion medium and *f* a form factor accounting for the shape and the volume of the (nonconducting) particles [461]. Thus, conductivity measurements provide information on particle formation, disappearance of particles, phase inversions, and particle swelling in heterophase reactions such as crystallization and emulsion and suspension polymerization [462-466].

Electrical resistance tomography is a rather new technique for on-line monitoring of chemical reactions of particulate systems in tank reactors. The voltage between individual electrodes of a system of electrodes distributed over one or several layers in the reactor wall is used to calculate an image of the electrical resistance distribution within the reactor which is indicative of changes of the dispersion state of multiphase systems [467].

Most applications of conductometry deal with monitoring of process streams rather than direct reaction monitoring. Typical application fields are drinking water purification and tap water monitoring, wastewater treatment, cleanness of ultrapure water in the electronics industry, distillation processes, neutralization and precipitation reactions, concentration monitoring of acids (e.g., in production of concentrated sulfuric acid), lyes, and salt solutions, and monitoring of process streams in dairies and breweries.

Electrostatic sensors can be used to on-line measure the mass median size of particles in a dilute-phase pneumatic suspension. The sensor configuration includes a wire-mesh electrode, signal conditioning electronics, and digital signal processing algorithms [468].

8.3. Potentiometry

Potentiometric techniques are characterized by the fact that electrode reactions at equilibrium are involved in the potential measurement. In potentiometry, the actual electrical current through the electrode is zero. The electrode potential cannot be measured directly but only as a difference with respect to the potential of another electrode (reference electrode). Electrode potentials and the potential difference between two electrodes can be calculated according to Nernst's equation (Eq. 42)

$$U_{\text{electrode}} \sim \frac{RT}{F} \ln \left(\frac{a_i}{a_{i,\text{ref}}} \right) \quad (42)$$

where R is the gas and F is Faraday's constant. The ion activities a_i can be activities of two different ions within the same solution (redox pair), activities measured with two different electrodes, or activities at two different concentrations or partial pressures.

Ion-Selective Electrodes. The swelling glass layer of ion-selective electrodes is designed to be sensitive to a certain type of ions and insensitive to others. This can be achieved by using membranes containing inorganic salts of the ions of interest (e.g., Na^+, K^+, Cu^{2+}, NH^{4+}, Cl^-, F^-, I^-). Conditioning of the mixture to a certain conductivity and pH level is a prerequisite for ensuring precise concentration measurements with ion-selective electrodes. Hence, the use of this type of electrodes for direct (in-line) insertion into a reaction mixture is limited [469], [470].

pH measurement is the most important and most widely used potentiometric technique in aqueous solutions or water-containing systems. Measurements of pH are crucial for monitoring processes in the chemical and pharmaceutical industries, the food and beverages industry, waste-treatment plants, environmental protection, and biochemical operations [471]. In particulate systems, the pH has a dramatic influence on colloidal stability (e.g., cosmetic products, emulsion and suspension polymerization). Care must be taken to take into account temperature variations of the reacting system because of the strong temperature dependence of electrode potentials.

pH measurements are easily performed with standard glass electrodes. For process applications, the most common pH-sensitive membranes consist of lithium glasses. Other alkali metal glasses are prone to increased hydrolysis and instability, especially in alkaline solution. Several types of glasses are available for different process environments (standard, highly alkaline, highly acidic, high temperature). Problems may arise with glass electrodes due to contamination of the surface by precipitation or film formation. Cleaning and maintenance of glass electrodes on a regular basis are critical for successful on-line pH measurements.

Glass electrodes with counterpressure are applicable for on-line monitoring of reactions up to temperatures of about 80 °C and pressures up to 60 bar. Mechanical instability is a major drawback of glass pH electrodes in high-pressure applications.

Solid-state ion-sensitive field effect transistor (ISFET) sensors show faster response, lower alkaline errors, and improved mechanical stability than glass electrodes. However, they also suffer from surface contamination. The applicability of ISFET pH sensors is limited to pressures well below 50 bar and temperatures up to 85 °C [472]. There is no solid-state sensor on the market applicable for pressures above 60 bar. An as-yet not commercially available ZrO_2 sensor for pH measurements under high pressure (83 bar) and high temperature (285 °C) is described in [473]. A number of different optical and fiber-optical pH sensors have been developed [474-477].

Redox Potential. The oxidizing or reducing character of a solution can be measured with (inert) precious metal electrodes (Pt, Au) relative to a reference electrode. Redox potential measurements are highly nonspecific because all redox couples of a mixture contribute to the potential. The redox potential also strongly depends on pH. Thus, the applicability of redox potential measurements is mainly limited to determining qualitatively, e.g., nitrites in wastewater (denitrification), cyanides, copper, and chromium in galvanic wastes, or chlorine in public swimming pools.

Potentiometric Oxygen Analysis. Solid-state electrolytes that exhibit ionic conductivity at elevated temperatures (> 500 °C) can also be used for potentiometric measurements. Porous ZrO_2 membranes covered with platinum grids have been used to determine oxygen in gases potentiometrically. Different oxygen concentrations on the two sides lead to a potential difference across the membrane in proportion to the difference in oxygen partial pressure.

8.4. Amperometry, Voltammetry, and Coulometry

Amperometric, voltammetric, and coulometric techniques are not so widely used as other electroanalytical methods for reaction monitoring. They are characterized by electrode reactions at polarized electrodes that are detected by current – voltage measurements. Because of the electrode reactions the electrodes have to be cleaned on a regular basis, and a certain fraction of the mixture under investigation is consumed during the measurement.

Applications include the amperometric determination of chlorine, dissolved oxygen, hydrazine, and ozone in pulp-bleaching baths; tap, industrial, and wastewater, amperometric monitoring of hydrogen peroxide in textile bleaching baths [478], the amperometric monitoring of gases and air at work places, the voltammetric determination of heavy metals in waste streams, and the coulometric analysis of sulfur compounds.

9. Miscellaneous Methods

9.1. Mass Spectrometry

In the 1990s, mass spectrometry (MS) emerged as technique for on-line analytical purposes. The method is highly sensitive and fast with an extraordinary molecular selectivity. The detection principle of MS is based on an ionization of chemical species followed by a separation of the fragments according to their mass-to-charge ratio (see ⟶ Mass Spectrometry). Due to the wide variety of ionization techniques, most types of sample can be analyzed by MS. Ionization techniques for process applications include electron impact (EI), resonance-enhanced multiphoton ionization (REMPI), microwave plasma ionization, thermal ionization, and electrospray ionization (ES). Direct capillary and membrane inlets are most commonly used for sample introduction. MS process applications are reviewed in [479-483].

In an increasing number of process applications MS is interfaced to pre-separation techniques such as GC or LC to improve resolution and selectivity in the analysis of complex (reaction) mixtures. Reduced costs, size, and complexity of the instruments have even made portable MS devices possible. Efforts have been undertaken within the last couple of years to miniaturize MS instruments ("MS on a chip").

The traditional on-line fields of use of MS are process gas stream and environmental gas analysis, environmental and wastewater monitoring, and monitoring of fermentation processes. Trace amounts of aromatics and chlorinated compounds in flue gases of industrial incinerators have been detected by REMPI-MS [484-486].

MS has also been applied to monitoring liquid-phase and gas-phase chemical reactions. On-line MS is useful for monitoring alkanes and alkenes in rubber production [487], monomers and solvents in polyethylene production [488], monitoring the photocatalytic degradation of phenol and trichloroethylene [489] or electrochemical polymerization of aniline [490].

The modern semiconductor industry relies heavily on MS process monitoring [491], [492]. MS can be used to monitor gaseous impurities in high-purity gases, to study plasma etching processes [493], molecular beam epitaxy, and chemical vapor deposition processes [494].

9.2. Densimetry and Dilatometry

The physical basis of densimetry and dilatometry is the mass density difference (if any) between initial reaction mixture and the final reaction product. As the reaction proceeds, this density difference leads to an increase or decrease in the density of the mixture $\varrho(t)$ and to an overall shrinkage or expansion, respectively, of the volume of the reaction mixture V. Density changes can be measured continuously with responses on the order of one measurement per second, while the repetition time for measurements of volume changes is in the millisecond range. Therefore, the extent of reaction can be calculated at any time if the amount of ingredients initially charged to the reactor and/or continuously fed to the reaction mixture is known.

The following factors must be considered in applying these techniques:

1. For a quantitative analysis of density changes, it has to be checked carefully whether the reaction mixture behaves as an ideal mixture or not; that is, does Equation 43

$$V_{\text{total}} = \sum_i V_i + V_{\text{excess}} \tag{43}$$

   with $V_{\text{excess}} = 0$ hold, where V_{total}, V_i, and V_{excess} are the volume of the reaction mixture, volume of component i, and excess volume, respectively.
2. Accurate densimetric and dilatometric measurements rely substantially on the accuracy of temperature control to be better than ± 0.1 K (in some cases even better than ± 0.01 K).
3. As with all other "integral" methods, a single variable (density, volume, temperature, pressure) is insufficient to describe multi-component reaction mixtures.

Density measurements are suitable for reaction monitoring of polymerizations (in bulk, solution, emulsion, suspension) because of the considerable density differences between monomers and polymers (Table 6). In a two-component system, the extent of reaction (e.g., conversion $x_r(t)$ in polymerizations) can simply be calculated according to Equation 44 by assuming ideal mixing behavior

$$X_r(t) = \frac{\frac{1}{\varrho_{\text{start}}} - \frac{1}{\varrho(t)}}{\frac{1}{\varrho_{\text{start}}} - \frac{1}{\varrho_{\text{end}}}} \tag{44}$$

where ϱ_{start} and ϱ_{end} are the density of the mixture at the beginning and end of the reaction.

Table 6. Densities of monomers and polymers at 20 °C

Monomer	Density, g/cm^3	
	Monomer	Polymer
Acrylic acid	1.051	1.37
Acrylonitrile	0.806	1.17
1,3-Butadiene	0.621	0.97
Butyl acrylate	0.899	1.08
n-Butyl methacrylate	0.886	1.06
Ethyl acrylate	0.924	1.12
2-Ethylhexyl acrylate	0.887	0.99
Ethyl methacrylate	0.914	1.13
Methyl acrylate	0.954	1.22
Methyl methacrylate	0.944	1.19

o-Methylstyrene	0.916	1.01
Styrene	0.906	1.04
Vinyl acetate	0.932	1.18
Vinyl chloride	0.911	1.39
Vinyl methyl ether	0.750	1.06

Most of the common principles to perform density measurements (pyknometer, buoyancy) are unsuitable for reaction monitoring. Methods that have been applied to process monitoring include hydrostatic pressure measurement, the maximum bubble pressure technique, oscillations of U-shaped tubes, cylinders or plates, and absorption of radioactive radiation or X-rays.

A rather robust technique is the measurement of the resonance frequency of a U-shaped tube (Fig. 21). This resonance frequency is a very sensitive function of the mass of fluid within the tube, and, hence, of its density. The densimeter has to be calibrated with a liquid of known density ϱ_{cal} that gives a period $T_{osc,cal}$ of the U-tube oscillations. The density of the mixture $\varrho(t)$ can be derived from the change of the period of oscillations $T_{osc}(t)$ provided the temperature T of the mixture is held constant (Eq. 45)

$$\varrho(t) - \varrho_{cal} = \text{const.}\left(T^2_{osc}(t) - T^2_{osc,cal}\right) \tag{45}$$

Figure 21. U-shaped tube for density measurements (courtesy of Anton Paar KG)

To obtain noise-free results, gas bubbles should be avoided while circulating the reaction mixture through the tube densimeter. In low-viscosity media, bubble traps can prevent bubbles entering the densimeter tube. A prerequisite for the application of Equation 45 is that the viscosity of the calibration liquid is roughly equal to the viscosity of the mixture because of its influence on the tube attenuation. The accuracy of density measurements with commercially available oscillating tubes can reach the range 10^{-6} to 10^{-7} g/cm^3. Applications of U-shaped tube density measurements to monitoring reactions can be found in [495-497].

In addition to gas bubbles and temperature uncertainties, film formation on the inner surface of the tube, formation of sediments, and clogging of the pipe may cause problems with this method. These problems can be partially overcome by the inverse arrangement: a tuning fork inserted into the mixture. Again, the change of resonance frequency of the fork is related to the density of the surrounding liquid, and the amplitude with which the fork oscillates (i.e., the attenuation) is a function of the viscosity of the medium.

The maximum bubble pressure technique is based on the pressure p_{bubble} of a spherical gas bubble of radius r at a capillary tip immersed in the reaction mixture at depth h (Fig. 22). This pressure is the sum of the hydrostatic pressure of the liquid above the capillary tip, and the pressure generated by the liquid – bubble interfacial tension γ

$$p_{bubble} = \varrho g h + \frac{2\gamma}{r} \tag{46}$$

where g is the acceleration due to gravity [498], [499]. Thus, p_{bubble} depends on both the immersion depth of the capillary tip into the liquid, and the capillary and, therefore, bubble diameter.

Figure 22. Schematic of maximum bubble pressure method

For density measurements, two capillaries of equal diameter are inserted into the mixture at different depths h_i beneath the surface. This leads to a difference of pressure readings Δp_{bubble} of the two capillaries, and

$$\varrho = \frac{\Delta p_{bubble}}{(h_1 - h_2)g} \tag{47}$$

The internal bubble pressure due to surface tension is identical for the two capillaries.

In addition, the two-capillary principle can also be used to measure the surface tension of the liquid. In this case, two capillaries of different diameters r_1 and r_2 are immersed into the liquid at the same depth and experience the same hydrostatic pressure but different internal pressures due to different bubble curvatures. Thus,

$$\gamma = \frac{\Delta p_{\text{bubble}}}{2\left(\frac{1}{r_1} - \frac{1}{r_2}\right)} \tag{48}$$

Corrections must be made to account for the influence of capillary forces and nonspherical bubble shapes [498]. In stirred or turbulent media, bubble shear-off may cause problems as well as coagulum formation or clogging of capillaries in film-forming media. The accuracy of bubble densimeters is on the order of 10^{-3} g/cm^3.

The hydrostatic pressure p_h of a liquid measured at a depth h is

$$p_h = \varrho g h \tag{49}$$

The hydrostatic pressure difference Δp_h between two pressure sensors at different depths of distance $\Delta h = h_1 - h_2$ is directly proportional to the liquid density

$$\varrho = \frac{\Delta p_h}{\Delta h g} \tag{50}$$

The physical basis of Equations (49) and (50) is essentially identical. In stirred or flowing media, the hydrodynamics may add considerable noise to the pressure readings of the sensor.

The absorption of radioactive radiation (including X-rays) depends on the molecular/atomic absorption coefficient, the density (concentration) of the ingredients, and the thickness of the material through which the radiation passes (path length d). After calibration of the absorption of both the source/cell/detector arrangement and the mixture, the density can be calculated according to

$$I_d \propto I_0 \exp(-\varrho d) \tag{51}$$

where I_0 and I_d are the intensity of the radiation source and the detected radiation, respectively.

Radiometric density determination is advantageous in systems under very high pressure and in corrosive media because neither the source nor the detector is in direct contact with the mixture.

The application of dilatometry to reaction monitoring is discussed in detail in [500]. Time-resolved measurements of volume changes for transparent and nontransparent samples with a laser scanning dilatometer show a simple linear relation between shrinkage and chemical conversion during epoxy curing [501]. In general, dilatometry is a very useful tool for academic research but only of limited value for reaction monitoring in (continuously stirred) industrial reactors.

9.3. Rheometry

The theory of rheology, instrumentation and applications are extensively described in [502-504] (see also ⟶ Rheometry, ⟶ Fluid Mechanics).

Various processes in the plastics industry are accompanied by viscosity changes of the reaction mixture:

1. Most of plastics manufacturing processes lead to a substantial increase of viscosity because of growing chains, branching, and cross-linking. Rheological characterization of plastics is essential for understanding and influencing their processability.
2. Curing reactions transform liquids into gels and solids. Thus, the resistance of the material to flow changes by orders of magnitude.
3. Melt flow index is an important parameter for monitoring and controlling reaction extrusion, reaction blending, and reaction injection molding [69], [70].

Increasing viscosity in noncross-linked systems can be related to the molecular mass and concentration of growing chains. For linear polymers, the bulk viscosity η is a function of the weight average molecular mass M_w similar to the Kuhn – Mark – Houwink equation for the intrinsic viscosity [η] of polymers in solution

$$\eta = K_\eta M_w^{a_\eta} \tag{52}$$

where K_η is a parameter that depends on interchain friction. The exponent a_η is about 1 – 2 for short chains, and increases to 3.4 above a critical molecular weight $M_{w,crit}$ [505]. Equation 52 holds also for branched polymers if M_w is replaced by gM_w, where the contraction factor g is defined as the ratio of the radius of gyration of the branched molecule to that of a linear molecule of the same weight average molecular mass.

In cross-linking reactions, the viscosity of the mixture increases dramatically while approaching the gel point [506], [507]. After reaching the gel point, the cross-linked reaction mixture behaves like a soft solid. For temperatures above the glass transition temperature T_g the mechanical properties of the material may be treated by rubber elasticity theory.

The viscosity of disperse systems depends on the volume fraction φ of disperse material, particle shape and size distribution, interparticular interaction, etc. For monodisperse spherical particles at low φ, viscosity is proportional to the volume fraction of the disperse phase

$$\eta = \eta_0(1 + 2.5\varphi) \tag{53}$$

where η_0 is the viscosity of the dispersion medium. For higher volume fractions and systems with dominant interparticle interaction, numerous theoretically based, semi-empirical, and empirical $\eta - \varphi$ relations can be found in the literature [508], [509]. Thus, viscosity reflects changes of particle number and size [510] in heterophase reactions (e.g. emulsion formation, emulsion polymerization, suspension polymerization, dispersion polymerization).

Principles and methods for on-line rheometry include rotational and capillary process viscometers (see ⟶ Rheometry), as well as the application of ultrasound (see Chap. Ultrasonic Methods), and tube or fork oscillations (see Section Densimetry and Dilatometry).

Widely used techniques for measuring melt viscosity in extruders are capillary viscometry and pressure drop analysis [69], [70], [511], [512]. The pressure drop Δp of melt flow through a nozzle is directly proportional to the melt viscosity according to the Hagen – Poiseuille law

$$\Delta p = -\frac{8\eta\bar{v}l}{R^2} \tag{54}$$

where $\bar{v}$, l, and R are the average velocity in the pipe, its length, and diameter, respectively.

9.4. NMR Spectroscopy

Nuclear magnetic resonance (NMR) spectroscopy (see ⟶ Nuclear Magnetic Resonance and Electron Spin Resonance Spectroscopy) is probably the most important spectroscopic technique for studying chemical structures. Signals of molecules and sub-units of molecules, and the signals of their various spatial arrangements and configurations are much more pronounced in NMR than in any other spectroscopical method. Nevertheless, NMR is still mainly an off-line technique because of elaborate sample preparation requirements, the instruments sensibility to temperature variations, the necessity of instrument tuning (magnet shimming, drift compensation), and the time required to run spectra. However, some recent developments in instrumentation (magnets, radio frequency source and detector circuitry), and the adaptation to flow cells have made NMR spectroscopy applicable to on-line analysis. A major advantage of NMR spectroscopy is the noninvasive character of the technique.

Most of the process measurements so far utilize pulsed NMR in which the free induction decay (FID) signal of magnetic-field aligned molecular spins after the application of a perpendicular radio frequency pulse is analyzed as a function of time. Network formation during the radiation-induced polymerization of *N*-isopropylacrylamide has been monitored by T_2 spin – spin relaxation time measurements [513]. The cure of an epoxy – amine system has been studied by NMR spectroscopy and compared to the results of alternative techniques such as ultrasound and dielectrics [514]. The solids content of rubber latex can be determined without any special sample preparation with a total measurement time of ca. 10 s by quasi-on-line application of pulsed NMR [515]. FID signals in combination with a chemometric technique (PLS) enable one to predict the styrene content in a butadiene – styrene resin [516]. Other applications include determination of hydrogen in various materials, and several solvents in gasoline.

High resolution NMR spectroscopy has been rarely applied to on-line analysis. Because of its natural abundance, ^{1}H NMR is superior to all other nuclei for process measurements. Applications include the determination of the total hydrogen content of hydrocarbons, the determination of crystallinity and melt index of polyethylene, cure dynamics, and copolymer formation monitoring [517], carbamic acid formation in supercritical carbon dioxide [518], the chemical equilibria and reaction kinetics of the formaldehyde – water – methanol system, the reactive gas absorption of CO_2 in aqueous solutions of monoethanolamine [519], are monitoring processes in refineries [520] and the emulsion polymerization of butyl acrylate [521]. Low-field NMR spectroscopy has been shown to be applicable to monitor the production of benzene [522].

CPAC: Center for Process Analytical Chemistry

CPACT: Center for Process Analytics and Control Technology

CRDS: cavity ring-down spectroscopy

CTAC: Control Theory and Applications Center

CVD: chemical vapor deposition

DGEBA: diglicidyl ether of bisphenol A

DGEBF: diglicidyl ether of bisphenol F

DDM: diaminodiphenylmethane

DLS: dynamic light scattering

DWS: diffusing wave spectroscopy

EWA: evanescent wave absorption

FDA: Food and Drug Administration

FFF: field flow fractionation

FID: free induction decay

FIR: far infrared

FOCS: fiber-optic chemical sensor

FODLS: fiber-optic dynamic light scattering

FOQELS: fiber-optic quasi elastic light scattering

FRA: frequency response analyzer

FT: Fourier transform

FTIR: Fourier transform infrared

GC: gas chromatography

GDCh: Gesellschaft Deutscher Chemiker

HPCL: high perfomance liquid chromatography

HT: Hadamard transform

HDC: hydrodynamic chromatography

IC: integrated circuit

IFPAC: International Forum for Process Analytical Chemistry

IR: infrared

LEC: liquid exclusion chromatography

LED: light-emitting diode

LIBS: laser-induced breakdown spectroscopy

LIPS: laser-induced plasma spectroscopy

MACC: McMaster Advanced Control Consortium

MCEC: Measurement and Control Engineering Center

NIR: near infrared

NMR: nuclear magnetic resonance

PCS: photon correlation spectroscopy

PLS: partial least squares

PREACH: Process Related Environmental Analytical Chemistry

PS: power source

PVC: poly(vinyl chloride)

QELS: quasi-elastic light scattering

QCM: quartz crystal microbalance

RIM: reaction injection molding

SAW: surface acoustic wave

SEC: size exclusion chromatography

SERS: surface-enhanced Raman scattering

SH: shear-horizontal

SLS: static light scattering

SRS: stimulated Raman scattering

UV: ultraviolet

VIS: visible

XPS: X-ray photoelectron spectroscopy

Symbols

***A*:** absorbance (extinction), instrument constant

A_R**:** reactor wall heat exchange area

a η**:** Kuhn – Mark – Houwink exponent

***B*:** instrument constant

***c*:** concentration

C_0**:** equivalent capacitance of free space

c_i**:** concentration of component *i*

$c_{p,cool}$**:** specific heat capacity of coolant

$c_{p,k}$**:** specific heat capacity of *k*th reactor feed

$c_{p,liq}$**:** specific heat capacity of jacket liquid

$C_{p,mixture}$**:** heat capacity of reaction mixture

$C_{p,tot}$**:** heat capacity of filled reactor

***d*:** distance, path length

***D*:** diffusion coefficient, dielectric displacement

d_p**:** particle diameter

d_{stir}**:** stirrer diameter

***E*:** electric field

f_{res}**:** resonance frequency

***f*:** frequency, particle size distribution function

***g*:** contraction factor

***G*:** shear modulus, distribution function

g_1**:** electric field autocorrelation function

g_2**:** light intensity autocorrelation function

***G*:** conductance

***h*:** depth

$\Delta H_{r,j}$**:** reaction enthalpy of *j*th reaction

***I*:** electrical current, light intensity

I_0**:** incident light (radiation) intensity

I_d**:** detected light intensity

I_l**:** light intensity at distance *l*

***K*:** bulk modulus, scattering coefficient

K η**:** Kuhn – Mark – Houwink parameter

***l*:** (optical) path length, distance

k_Q**:** heat transfer coefficient

K_b: Boltzmann constant

m: refractive index ratio

m_k: mass of component k

m_{cool}: mass of coolant

m_{liq}: mass of jacket liquid

M_w: weight-average molecular mass

$M_{w,crit}$: critical weight-average molecular mass

n: refractive index

n_m: refractive index of medium

n_p: refractive index of particle

N_v: stirrer speed

p: pressure

P: polarization

p_0: pressure amplitude

p_{bubble}: bubble pressure

p_{gel}: gel point

p_h: hydrostatic pressure

p_x: pressure amplitude at distance x

P_0: power number

q: scattering vector

Q_{acc}: accumulated heat

Q_{cal}: heat generated by calibration heaters

Q_{el}: heat generated by electrical heaters

Q_{feed}: heat generated by material feed

Q_i: sources and sinks of heat

Q_{loss}: heat losses

Q_{osc}: heat of forced temperature oscillations

Q_r: heat of reaction

Q_{reflux}: heat flow over reflux condensor

Q_{stir}: heat input due to stirring

Q_{trans}: heat transfer through reactor wall

R: reflection coefficient, tube diameter

r: radius

r_h: hydrodynamic radius

R_j: reaction rate of *j*th reaction

t: time

T: transmission coefficient, temperature

δT: amplitude of temperature oscillations

T_1: outer reactor wall temperature

T_2: inner reactor wall temperature

$T_{cool,in}$: coolant temperature (inflow)

$T_{cool,out}$: coolant temperature (outflow)

T_g: glass transition temperature

T_J: reactor jacket temperature

$T_{J,in}$: jacket temperature (inflow)

$T_{J,out}$: jacket temperature (outflow)

T_k: temperature of *k*th reactor feed

T_{osc}: period of tube oscillations

$T_{osc,cal}$: period of tube oscillations filled with calibration liquid

T_R: reactor temperature

u: sound velocity

U: electrical voltage

u_0: sound velocity of reference component

U_0: initial electrical voltage

$(\Delta u / \Delta c)_i$: sound velocity-concentration coefficient *i*

$u_{l,liq}$: longitudinal sound velocity of liquids

$u_{l,sol}$: longitudinal sound velocity of solids

u_{mix}: sound velocity of a mixture

$u_{tr,liq}$: transversal sound velocity of liquids

$u_{tr,sol}$: transversal sound velocity of solids

U_x: electrical voltage at distance *x*

V: volume

V_{excess}: excess volume

V_i: volume of component *i*

V_r: volume of reaction mixture

V_{total}: total volume

***x*:** distance

x_r**:** monomer conversion

X_r**:** calorimetric conversion

***Y*:** complex admittance

***Z*:** acoustic impedance, complex impedance

Z'**:** real component of complex impedance

Z''**:** imaginary component of complex impedance

α**:** sound attenuation

α_{liq}**:** sound attenuation in liquids

β**:** adiabatic compressibility

δ**:** loss angle

ε**:** decadic extinction coefficient

ε^***:** dielectric permittivity

ε_0**:** free space dielectric permittivity

ε_∞**:** high frequency dielectric permittivity

ε'**:** storage component of dielectric permittivity

ε''**:** loss component of dielectric permittivity

$\varepsilon^*_{dipolar}$**:** dipolar reorientation contribution to ε^*

Υ**:** surface tension

Γ**:** decay constant

η**:** (bulk) viscosity

η_0**:** viscosity of dispersion medium

η_s**:** shear viscosity

η_v**:** volume viscosity

Φ**:** wave phase, volume fraction

Φ_r**:** phase shift between temperature oscillations

Λ**:** conductivity

λ**:** wave length

λ_{exc}**:** excitation wave length

λ_m**:** medium light wave length

λ_Q**:** heat conductivity

ν**:** frequency (of light), average velocity

θ**:** scattering angle

ϱ**:** density

ϱ_{cal}: density of calibration liquid

ϱ_{end}: density at reaction completion

ϱ_{mix}: density of reaction mixture

ϱ_{start}: density at reaction start

σ_{dc}: dc conductivity

τ: oscillation period, relaxation time, optical transmittance (turbidity)

ω: oscillation (angular) frequency

ω_{max}: frequency at loss maximum

1. Introduction

While advances in modeling and predictive methods have greatly expanded the range and utility of theoretical research, there still can remain a significant degree of uncertainty in the final results before a major investment is justified. Small-scale laboratory tests help minimize this uncertainty but are fraught with risk due to the small scale and manual, batch simulation of most of the process steps. Hence the concept of piloting the process in a miniature unit in a way which more closely simulates the actual process plant. Pilot plants have evolved from multistory semi-works units, designed for one-tenth of final process scale, to microunits, which fit in larger laboratory hoods. Their cost and complexity often belie their small size and great utility.

The piloting process often occurs several times over the life of a research program, Table 1 shows a sequence of this piloting that might be part of a research program. Depending on the complexity of the process, the results of subsequent steps, and the organization's experience and comfort with the process and results, some of these steps may be eliminated. Recycle and feedback between each step is also possible when problems arise or concerns refuse to be resolved. As each step along this path involves an exponential increase in the resources, time, and money required, there is a strong incentive to progress to the next stage as soon as is practical. Conversely, there is a need to minimize the amount of recycling as the project progresses through the various steps to the commercial unit. While this rapid progress is desirable, the consequences of skipping a necessary preliminary stage or failing to fully understand the results of the previous stage can be devastating. Significant time and resources can be wasted at the next stage if it is focused along an incorrect or at least nonoptimum path. A substantial amount of time and money has progressively been invested, and any desire to change the process to make minor improvements must be resisted. At some point the decision must be made that the remaining unanswered process questions are acceptable risks.

Table 1. Typical research program steps

Step	Intention
Concept	Initiate ideas/concepts to be investigated
Basic research	Determine basic feasibility of concept
Preliminary economic evaluation	Determine if economic incentive is sufficient to proceed with investigation
Laboratory research	Develop basic data
Product evaluation	Evaluate product suitability
Process development/preliminary engineering	Produce preliminary design of actual commercial plant, resolving process questions as they arise
Pilot plant study	Prove basic reliability of proposed process or process design
Demonstration unit	Demonstrate process feasibility on small commercial scale
Prototype unit	Demonstrate process feasibility on small commercial scale
Commercial plant	Produce and sell a product at a profit

In today's climate of rapid change, timeliness can be as important or more important than minimizing the risks associated with a new product or process. Examples include securing a new mar-

10.1002/14356007.c19_c01

ket with a totally novel product or attempting to secure a patent position before a competitor. In this situation, the decision may be made to proceed to commercialization earlier than desirable, prior to satisfactorily resolving all design concerns. This often usually requires a more conservative (and more expensive) design approach, results in a significantly longer start-up, or produces a first unit plagued with operational difficulties. Resolving significant problems during start-up or in an operating unit, while feasible, is risky, expensive, and time-consuming. Rarely is it more effective than additional research.

A pilot plant is a collection of equipment designed and constructed to investigate some critical aspect(s) of a process operation or to perform basic research. It is a tool rather than an end in itself. A pilot plant can range in size from a laboratory bench-top unit to a facility approaching the size of a commercial unit. The purposes for its construction and operation can vary widely; they include:

- Confirming the feasibility of a proposed process
- Providing design data
- Determining the economic feasibility or a new process
- Determining optimum construction materials
- Testing the operability of a control scheme
- Determining the extent of plant maintenance
- Producing sufficient quantities of product for market evaluation
- Obtaining kinetic data
- Screening catalysts
- Proving areas of advanced technology
- Providing data for solutions to scale-up problems
- Providing technical support to an existing process or product
- Assessing process hazards
- Determining operating costs

The need for a pilot plant is a measure of the degree of uncertainty in developing a process from the research stage to a full commercial plant.

2. Classification of Pilot Plants

Pilot plants can be categorized by a number of different criteria. Size is the most common classification as it is the most uniformly proportional to construction and operating costs; a common classification is shown in Table 2. While a common classification, this approach shows little but a range of sizes and costs. The pilot plant's degree of automation is another classification as instrumentation typically represents large portion of the initial construction and annual operating costs; a common classification is shown in Table 3. While more useful in some respects, this classification is also primarily an indication of cost and complexity. In addition, the high cost of operating labor and the difficulties in manually a process while acquiring accurate data has forced the level of automation of virtually all but the simplest new pilot plants to be increased to such an extent that most fall into the highest automation class. Other classifications based on strategic purpose and/or design philosophy exist [1]. These are often more useful as shorthand methods of communicating useful concepts about pilot units in general. All these classifications are elastic.

3. Scale-Up

Scale-up is the process of developing a plant design from experimental data obtained from a unit orders of magnitude smaller (see also → Scale-Up in Chemical Engineering, Chap. 4.; → Process Development, Chap. 3.). This activity is considered successful if the commercial plant produces the product at design capacity, cost, and quality. This step from pilot plant to full-scale operation is the most potentially risky of all the phases of new process development, as the highest expenses are committed when the greatest risks occur.

Process plant design has come a long way from the early 1930s, when process designers were limited to rules-of-thumb that a process facility should not be scaled-up more than tenfold [2].

Table 2. Typical classification of pilot plants by size

Class	Characteristics	Cost range
Micro-unit or bench-top unit	Small size ($< 2\,m^2$), typically found in a hood or on a bench top Small tubing used throughput (3 – 6 mm diameter) Small feeds (Small size (< 4 L)	\$ 10 000 to \$ 100 000
Integrated pilot plant	Larger size (usually $10 - 25\,m^2$), located in open bay, walk in hood, or containment cell Tubing and small (13 – 25 mm diameter) pipe used Fully automated Feed and product systems with limited capacity usually included	\$ 50 000 to \$ 500 000
Demonstration or Prototype Unit	Very large size ($> 250\,m^2$), usually in a dedicated building or area Pipe used extensively Fully automated usually with a dedicated computer system Feed and product systems, including significant storage capacity included	\$ 1 000 000 and up

American Oil's Ultracracking unit at Texas City, for example, was designed with data from a small pilot plant with a scale-up factor of 80 000 [3]. However, many scale-ups still require smaller ratios, albeit greater than 10 : 1, particularly for new processes.

Scale-up problems exist for many reasons, including basic equations unsolvable by known mathematical techniques, interconnected physical and chemical process aspects resulting in coupled basic equations, solutions used on the pilot plant that are not suitable on the commercial scale, and unknown equipment performance at sizes never used before. Discussions of scale-up problems and solutions are available in [2–9]. While successful pilot plant operation does not guarantee successful commercial plant operation, it considerably decreases the risk. All stages of a research program should confirm good scale-up practices are being followed.

4. Planned Pilot Plant Experimentation

Planning the experimental program is an important step in determining the type of pilot plant required. This step should be performed as soon as the research program objectives are defined, as the type of experimental program required sets, to a large degree, the total program cost, the type of pilot plant required, and the required pilot plant operation. Hence planning the experimental program is one of the major effects on the economic justification of research programs. Planned experimentation

- Reduces the number of tests required – a key factor in controlling annual costs as it is not unusual for the annual operating costs of a pilot plant to be two to three times the initial construction costs.
- May alter the design or show that a pilot plant is not the best place to obtain some of the desired information.
- May highlight the need for more laboratory work to support the pilot plant operation. Laboratory work is less costly and frequently will give insight to correlations or models for the process to be studied in the pilot plant.
- Is instrumental in determining the overall project schedule.

Hence, the early inclusion of planned experimentation in any research program is vital. Pilot plant design specifications should be established only after careful experimental program development, as decisions on the accuracy of instruments, analyzers, and other equipment should be based on the planned experimental requirements, not haphazard assumptions. Flexibility and versatility are important but costly; when provided unnecessarily or too profusely, they can result in a unit that is expensive and time-consuming to construct and start up, as well as difficult or impossible to operate successfully. There is always a tendency to ensure the design covers any possible eventuality as well as to try to maximize the unit's use across future programs. Both tendencies often result in overly complex units, which often make achieving the original goal more difficult, costly, and time-consuming.

Statistical designs for experiments maximize information and reduce research time and costs. These techniques are less likely to miss synergistic factors affecting performance or product quality, minimize the element of human bias, eliminate less productive avenues of experimentation by taking advantage of previous data, and

reduce the number of pilot plant runs needed to define the effects of variables. Overall, statistical designs increase the confidence level in the experimental results. Additional information is available in [9–17], [70].

Table 3. Typical classification of pilot plants by degree of automation

Degree of automation	Characteristic	Cost of instrumentation ∗
Manual	]All process conditions set and monitored by operators Poor repeatability Loose process control	< $ 2000
Local control	Most important variables monitored by dedicated controllers Tighter process control Possibly some data-gathering instrumentation	$ 10 000 – $ 20 000
Mixed systems	All variables monitored by controllers (may be local or distributed) with some computer-controlled or -monitored Usually data gathering provided via "smart" data logger or computer Usually older system upgraded to more modern standards	$ 15 000 – $ 30 000
Automated	All or majority of systems computer-controlled Tightest process control May be supervisory or direct digital control High repeability Lowest operating labor Most batch operations may be automated Data gathering integral part of control system	$ 20 000 – $ 60 000

∗ Costs include installation of equipment but not field wiring and are based on a typical medium-sized pilot plant of 10 – 20 control loops. For smaller units (less than 10 control loops), reduce the above by 25 – 40 %; for larger units (20 – 40 control loops) increase costs by 50 – 100 %.

5. Pilot Plant Design

A pilot plant's design affects all aspects of its life and performance including its cost, operability, and effectiveness. While all operating ranges may not yet be fully defined at the initial design stage, a realistic preliminary range is required before the design is commenced, as is a clear definition of the pilot plant's purpose. The first step in pilot plant design is to determine whether to design a pilot plant for process modeling or problem investigation. Modeling the process involves reproducing the specific unit operations on a smaller scale. This promotes safe scale-up, minimizes design time, and reproduces all process operations of interest. It is usually expensive since all operations are reproduced, not just the most important ones. Investigating the problem involves designing a pilot plant to look at a specific area of interest. In this case, the pilot plant may not resemble the commercial operation. While this approach is usually cheaper and quicker, it carries the inherent risk of missing the real problem and producing nothing of value. Several references have addressed each type of approach [1], [18–21].

Pilot plants may be designed with conventional design techniques that mimic commercial process design. This generally provides for a safe and operable design, as the basic methodology is known and the effectiveness of the final results have been proven previously. While safer, this approach is not always feasible: the proposed scale of the pilot plant operation may be completely outside the range of all commercial design techniques, the design suggested may not be economical on the scale envisioned or in the location proposed, or copying the commercial design may carry some inherent limitations that adversely impact operations at ranges or conditions which are of interest in the pilot plant but not in the commercial plant. An alternative approach is to use a design methodology oriented to the pilot plant, by using many conventional design techniques, but trying to maximize the advantages of the pilot plant operation with regard to scale, techniques, and operation. Advantages include economic savings due to reduced equipment, construction, and operating costs; economical and efficient ways around otherwise expensive problems; increased simplicity of operation, resulting in reduced maintenance and operating staff, and improved process understanding through use of specialized equipment. The lack of published design information, however, raises the risk factor; hence, the quality of the final design is very dependent on the skill level and experiences of the design organization/engineer. A significant problem is the limited number of in-house pilot-plant-specific design organizations and truly pilot-plant-specific contractors. This makes using the alternative approach sometimes riskier, except for larger organizations with the requisite in-house resources

or after a diligent and often expensive contractor evaluation and qualification.

6. Methods of Estimating Pilot Plant Costs

Pilot plants costs range from US \$ 10 000 to 10×10^6, but most are commonly in the \$ 50 000 to \$ 250 000 range when an existing facility is available to house them. There are three basic methods for estimating the costs to design and construct a pilot plant; similarity, cost ratios, and detailed labor and materials. Similarity involves estimating the cost of the pilot plant on the basis of costs to design and construct a similar unit. While the fasted method, it is the least accurate, with errors of $\pm 100\,\%$ not uncommon. As pilot plants are generally built for new processes or process improvements, most are more or less unique. Few units are ever similar enough for good cost estimation. Cost ratios develop the cost estimate by relating the overall cost of the pilot plant or a part of the pilot plant to a known factor such as the cost of major process equipment, the number of control loops, the size of the equipment, or a variety of similar factors. The cost estimate is built up by using the ratios to develop the cost of the entire unit, individual equipment, or separate subsystems, depending on how detailed a cost ratio estimate is made. Unfortunately, cost ratio information, while widespread as a plant-estimating tool, is rarely available for pilot-plant-scale equipment. The lack of a large data pool also renders much of what is available suspect with regard to its overall accuracy. Depending on the type of cost ratios used and the experience of the personnel making the estimate, accuracies of $\pm 25-50\,\%$ are typical. Cost ratios can be used more accurately if they are restricted to small subsystems, as numerous information is available in this area [22]. This, however, usually requires a substantial increase in effort. Detailed labor and material estimation involves breaking the pilot plant construction down into a detailed series of small tasks and estimating the labor and materials required for each separate task. This estimation may be performed by in-house or contract engineers, obtained from contractors, or solicited, or solicited via bids or consulting. This method can produce estimates with accuracies of $\pm(10-20)\,\%$ but requires more effort than either of the previous methods. See Table 4 and [1], [22–28], [71] for further information.

In general, similarity or general cost ratios estimates are used for developing screening estimates when an estimate is required quickly and a lower accuracy is acceptable. Detailed cost ratios or detailed labor and materials estimates are generally developed prior to actual appropriation of funds so as to have a more accurate estimate for budgeting and cost control.

The costs for operating a pilot plant are a summary of the costs of the feedstock, product disposal, utilities, operating labor, spare parts, maintenance, and support services. Major efforts to reduce operating costs have focused on reducing the operating labor through automation and unattended operation [1], [29–37], as well as controlling waste-disposal costs by careful design and planning [1], [38].

While often overlooked or, at best, cursorily estimated in advance, operating costs outweigh construction costs within one to three years. Hence, investments in reducing these costs, while adding to initial unit costs, are generally prudent.

7. Pilot Plant Space

Pilot plant space can be divided into several basic types: separate buildings, containment cells or barricades, open bays, walk-in hoods, and laboratory areas. Space is often selected more for availability than suitability or long-term operability. This can lead to significant problems later. For a more detailed summary of the advantages and disadvantages of each type of space and a full discussion of the impacts, see [1]. The space required for a pilot plant will vary tremendously with its size and type. A small unit may require only part of a laboratory (perhaps $5-10\,m^2$) while an "average" pilot plant may require a large room or building (perhaps $500-2000\,m^2$), excluding extended feed or product storage.

Pilot plant space often requires significant exhaust ventilation, large numbers of utilities, and special power and climate control. Hence, it is expensive to construct and even more expensive to operate.

Table 4. Pilot plant cost estimating techniques

Method	Accuracy range	Information required	Time to develop ∗ (weeks)
Similarity	± (50 – 100) %	Costs of similar unit Differences from proposed unit	< 1
General cost ratios	± (25 – 50) %	All scaling elements (such as control loops, size or similar factors) Different from ratio basis	1 – 2
Detailed cost ratios ∗∗	± (15 – 30) %	Detailed P & ID Complete equipment list Preliminary layout	4 – 12
Detailed labor and materials	± (10 – 20) %	Detailed P & ID Preliminary electrical and instrumentation drawings Complete equipment and materials list Preliminary layout	4 – 12

∗ After preliminary design is completed. ∗∗ The difference between a general and a detailed cost ratio cost estimate is the level of detail involved. A general cost ratio estimate might develop the total cost for the pilot plant control system – or even the pilot plant – from the number of control loops. A detailed cost ratio estimate would estimate the cost per loop based on the type of loop. The rest of the estimate would have to be generated by a large number of similar ratios.

8. Scheduling

A major concern in all pilot plant work is minimizing the time involved between project inception and meaningful data generation. Typically, an "average" pilot plant requires six or eighteen months to progress through this process, as shown on Table 5. This lead-time can be reduced significantly through careful planning, purchasing long-lead-time items early and various construction techniques. Reference [1] gives typical lead times for major pieces of equipment for planning purposes. Design time can be reduced if standardized designs have been developed in advance for common subsystems. For a discussion of problems with crash pilot plant projects, see [69].

Table 5. Typical lead times

Task	Time, months
Design, materials, procurement, scheduling	3 – 12
Construction	3 – 12
Start-up (up to and including first actual run)	1 – 6

9. Pilot Plant Control System and Instrumentation

Defining the requirements for a pilot plant control system is often difficult, as data on research-scale systems is rarely available, often contradictory, and usually less than convincing. Using the more readily available process control system data often results in a system that is too large, too complex, and more expensive than is really required for a pilot plant. The plethora of small PC-based control and data-acquisition systems on the market makes evaluation of all possible alternatives a tedious and time-consuming task. The evaluation process is not straightforward and requires experience and skills not always readily available to a research organization. Personnel inexperienced in either instrumentation systems or pilot plant operations frequently perform the control system design. The isolated and often intermittent nature of pilot plant operations also inhibits evolution and promotes individual unique installations. This complicates the selection process.

Automatic instrumentation systems for pilot plant were originally based on small stand-alone analog devices. The trend in these devices has been towards smaller and less expensive units with more flexibility; this increases their suitability for pilot plant instrumentation systems. Computer-based control systems, once restricted to large process plant applications, are now commonly available in sizes and costs suitable for most pilot plant operations. The additional data gathering and work-up capabilities of these systems make them so attractive that they have largely displaced analog systems for all but the simplest applications. Computer-based systems continue to grow smaller and less expensive. Analog equipment is also being redesigned as small stand-alone digital units. This is blur-

ring the distinction between computer-based and stand-alone systems. Most organizations are installing computer-based systems on all but the simplest pilot plant.

Three types of computer control systems are commonly used for pilot plant control systems. The first is a centralized system, historically based on a minicomputer or occasionally a mainframe but now increasingly network based. These systems have large storage capacities, substantial memories, and numerous associated equipment. They typically control all the pilot plants in an area or facility. Centralized systems are economical if a large number of units are involved but are less common due to their high installation and maintenance costs, as well as the limitation that any failure of the central system shuts down all the pilot plants involved. The growth of in-house networked computing systems has reversed this decline and resulted in a greatly increased growth in this area. The resulting systems work like stand-alone PCs but have the advantages of central systems. In effect they are starting to become the low cost DCS systems (see below) pilot plant organizations have been searching for.

Stand-alone computer systems, usually based on a personal computer (PC) or programmable logic controller (PLC), provide a separate system for each pilot plant. This allows for economical expansion for new units, separates pilot plants completely for maintenance and troubleshooting, and often has the lowest initial cost. Standardization can be a problem, and software control, data gathering, and storage packages can be limited in size, scope, and capability; these are usually acceptable trade offs.

Distributed control systems (DCS) are a hybrid of the previous systems, with stand-alone computers for control and data gathering at each pilot plant, tied together with one or more higher level computers for data storage and work-up. Typically more expensive than either central systems or stand-alone computers, distributed control systems have the advantages of both systems. This approach is preferred for pilot plants when it can be economically justified, usually for larger research facilities or very large demonstration units. As mentioned above, networked, stand-alone PCs are beginning to lower the overall costs to the extent that many organizations will be able to take advantage.

For further information on the different systems, including a more detailed discussion of their costs, advantages, and disadvantages, see [1], [40]; for information on actual experience, see [32], [34–36], [41–47], [72], [73].

The support resources necessary to service, repair, and calibrate the control system must also be considered when selecting a system; they are considerable and can be estimated from the literature [48–50].

Pilot plants are usually heavily instrumented compared to commercial plants. For further information on some of the more common pilot plant instrumentation see [1], [51], [74].

Analytical instrumentation for pilot plants are divided into two general classes, off-line and on-line. Off-line analysis is a batch operation requiring sample taking, handling, and storage followed by analysis later in time, frequently in another location. It interferes least with the process, is commonly less expensive, and allows the analysis to be performed under rigorously controlled conditions. (Some analyses cannot be made in any other manner due to equipment limitations, although this is becoming less common). Disadvantages include the difficulty in taking, handling, and storing representative samples and the inability to modify process on a real-time basis due to the time lag between sampling and analysis.

On-line analysis is often more expensive and difficult to set up initially but can be more accurate and reliable if performed properly on-line monitoring of Chemical Reactions. On-line analyzers can also be used to provide real-time control of a secondary process variable such as severity or conversion, as opposed to controlling a primary variable, such as temperature [36], [52]. The growth in this area suggests that fewer and fewer analyses will be done off-line, and that these will be restricted to difficult or capital intensive tests [75].

The maintenance of analytical instrumentation requires trained personnel and is time-consuming [39], [40]. An additional problem is the necessity of frequently checking the calibration of the analysis instrumentation and recalibrating if required.

Stand-alone data-gathering instrumentation, once common in pilot plants, has been virtually replaced in all but the simplest pilot plant by a

data-gathering computer, usually used for process control as well.

10. Feed and Product Handling

One of the most vexing aspects of pilot plant work can be feed and product handling, as a pilot plant is neither designed nor operated as a closed loop system like a commercial plant. Feedstock is often obtained by different methods with different purity. Products are often not separated or processed as completely. The problems involved in handling and storing feed and product materials can often rival the pilot plant process problems in difficulty.

The toxicity of both feeds and products must be carefully considered during the preliminary design stages [53], [54], especially if they contain known or suspected carncinogens. Special testing may be required prior to operation to determine the toxicity of unknown materials.

Provision must be made for sufficient storage of both feeds and products while minimizing operator-handling time. Sufficient surge time must be available in both feed and product systems to minimize the need for contained close operator attention. High level alarms and cutoffs should be installed on all product vessels that could overflow; low-level alarms and cutoffs should be considered for all feed vessels that could be emptied. Vented products must conform to all existing federal, state, and local environmental regulation, as well as good engineering judgement. This may require scrubbing or neutralization, incineration, flaring or similar measures. Care is required to ensure emergency venting is adequately dimensioned, selected, and installed and that products are vented to an appropriate height and/or location. The area electrical classification around the unit must be carefully evaluated and selected. If a pilot plant is located in an electrically classified area, handling of flammable feeds and products becomes more difficult. The same is true if toxic materials are used in a poorly ventilated area. For a further discussion of some of these concerns, see [68].

11. Pilot Plant Start-Up

Pilot plant start-up is different from major process plant start-up due to the smaller scale of he unit, smaller resources committed, lack of advance start-up planning, and limited experience with the pilot plant process and operation. Yet is it often as complex and demanding a task. The resultant underestimating, limited planning and staffing often creates problems.

The key a successful pilot plant start-up is advance planing; at least 6 – 8 weeks before project completion to allow identification of problem areas and concerns in time for successful resolution. A detailed start-up plan should be developed, listing each task to be performed in chronological order. The start-up plan then allows a list of required resources and a tentative start-up schedule to be developed. A successful start-up requires this advance planning as well as adequate trained and experienced personnel with a variety of skills. Many companies have found that a specialized start-up group is a major asset if pilot plant work is regularly done. Safety is also a major concern during start-up, as interlock systems are not fully functional and equipment and subsystems are being energized for the first time. For a more detailed discussion of pilot plant start-up including developing a start-up plan, see [1].

Pilot plant start-up costs vary widely; the costs booked to the start-up as well as the extent of the commissioning activities labeled as "start-up" varies widely among organizations. Typical costs range from 5 to 50 % of construction cost, with 10 to 20 % typical. Start-up durations also vary greatly, but a range of one to three months is common, depending on the personnel training and expertise. One often-overlooked anomaly is the increasing time required for computer programming during start-up. This is due to the large increase in automation for most units. Despite "user-friendly" systems, programming still often requires special training and skills not easily or economically developed in operating personnel. Another problem is skill retention, as trained operating personnel typically lose their edge when called upon to use programming skills only very intermittently. Hence many organizations are being forced to provide specialists who routinely provide this service to a

larger base. When unrecognized or unavailable, this can lead to significant start-up delays.

12. Safety In Pilot Plant Design And Operation

Pilot plants are often more hazardous than process plants, even though they are smaller in size. This is due to a tendency to relax standard safety review procedures (based on he small scale, exceptionally qualified personnel involved, and the experimental nature of the research operations), the lack of established operational practice and experience, the lack of information regarding new materials or processes, and the lack of effective automatic interlocks (due to the frequently changing nature of pilot plant operations, the desire for wide latitude in operating conditions, and the lack of full-time maintenance personnel). To minimize these concerns, most organizations require a formal series of safety reviews and hazard analysis for each new or modified pilot plant. At a minimum, this involves analyzing the proposed pilot plant before construction to identify and eliminate any potential hazards. This includes toxicity or flammability concerns, feed or product handling, disposal problems, relevant regulations, and potentially harmful reactions. The exact type and timing of these reviews varies between organizations; see [1], [39], [40], [68] for a further discussion.

The pilot plant must also be carefully designed so that its control and safety systems are fail-safe and any unexpected equipment or utility failure brings the unit into a safe and de-energized condition. Unexpected or rapid process changes, if they can herald or lead to dangerous conditions, such as runaway exothermic reaction, should be continuously monitored by appropriate instrumentation and suitable automatic action provided.

Further information can be found in [1], [55–68].

1. Abbreviations and Glossary of Special Terms

Allele:	=	one of two or more variants of a gene
Amplicon:	=	PCR-generated specific DNA fragments of defined length
Amplification:	=	multiplication of DNA or RNA fragments by PCR
Annealing:	=	hybridization of oligonucleotides to complementary sequences of DNA
AP-PCR:	=	arbitrarily primed PCR, synonymous for RAPD
ARMS:	=	amplification refractory mutation system
ASO:	=	allele-specific oligonucleotide
bp:	=	base pair; complementary nucleotides that form characteristic bonds
Blunt end:	=	end of double-stranded nucleic acid molecule where both strands have the same length
Booster PCR:	=	PCR technique for increased specificity; reaction is started with low primer concentrations and primer concentration is increased during PCR

CCD: = charge-coupled device
CCM: = chemical cleavage of mismatches
cDNA: = complementary DNA copy of a mRNA molecule synthesized by reverse transcriptase
Complementarity: = specific binding of adenine to thymine (or uracil) and guanine to cytosine between two antiparallel strands in nucleic acids molecules
DAF: = DNA amplification fingerprinting; PCR with short random primers generating a set of unspecific amplicons
Denaturation: = melting of double-stranded nucleic acids in single-stranded molecules by temperature or chemical agents
DGGE: = denaturing gradient gel electrophoresis
Dideoxynucleotide: = analogon to deoxynucleotide without 3′-hydoxy-group; synthesizing of DNA molecules with such nucleotides terminates elongation
dNTP: = deoxynucleotide
dsDNA: = double-stranded DNA
ERIC-PCR: = enterobacterial repetitive intergenic consensus PCR; fingerprinting technique for characterization of microbes
Exonuclease: = nucleic acids restricting enzyme; restriction starts at the 3′- or 5′ end of the molecule
FRET: = fluorescence resonance energy transfer
GMO: = genetically modified organism
HLA: = human leukocyte antigen
Homology: = identical DNA or RNA sequence in two different molecules
Hot start PCR: = PCR with two compartments initially separated by wax; amplification is started at elevated temperatures when the wax layer melts and the two compartments are mixed
Hybridization: = linking of two single stranded nucleic acid molecules by complementary base pairs
IMS: = immunomagnetic separation
LED: = light emitting diode
MHC: = major histocompatibility complex
MUX: = multiplexer
Nested PCR: = PCR technique for increased sensitivity and specificity; two consecutive PCR reactions are performed; the amplicon of the first reaction serves as template in the second PCR
PEST: = primer extension PCR
Plasmid: = circular DNA molecule which carries genetic elements permitting its own autonomous replication in bacteria and yeast; sometimes coding for characteristics of microbes like resistance to antibiotics
Primer: = oligonucleotide which anneals specifically to complementary DNA; primer serve as starter molecules for the elongation of complementary DNA strands by polymerases
Probe: = DNA, RNA or oligonucleotide that binds (hybridizes) to complementary single stranded DNA or RNA
Processivity: = number of nucleotides incorporated by a polymerase before the enzyme drops off the DNA matrix
Proofreading: = capacity of polymerases to recognize and substitute incorrect bases while synthesizing new nucleic acid molecules
RAPD: = random amplified polymorphic DNA; applied for differentiation of species or subspecies
REP-PCR: = repetitive extragenic palindromic PCR; fingerprinting method
Restriction enzyme: = enzymes restricting DNA at specific palindromic sequences
Reverse transcriptase: = enzyme that synthesizes single stranded DNA complementary to RNA matrix
RFLP: = restriction fragment length polymorphism
rRNA: = ribosomal RNA
RT-PCR: = reverse transcription followed by PCR
Satellite DNA: = repetitive DNA elements in eucaryotes; number of repetitions varies individually
SSCP: = single strand conformation polymorphism
ssDNA: = single-stranded DNA
Sticky end: = double-stranded nucleic acid molecules with 3′ or 5′ protruding ends generated by restriction enzymes
Stringency: = conditions (temperatures, salt concentrations) influencing specificity of PCR
Template: = matrix DNA for the synthesis of new DNA molecules by polymerases during PCR
Touch down PCR: = PCR with particular temperature conditions for increased specificity
UNG: = uracil-N-glycosylase
UPGMA: = unweighted pair group method, averages
VNTR: = variable number of tandem repeats
XL PCR: = extra long PCR for amplification of large DNA fragments

[Top of Page]

2. Introduction

Polymerase chain reaction (PCR) technology enables scientists to rapidly generate large amounts of genetic material from trace amounts which would otherwise be too small to analyze. Or in other words: PCR is a method to amplify minute amounts of particular DNA fragments (in the most extreme case one molecule) from a complex mixture of nucleic acids (DNA, RNA) so as to analyze the fragment or to make it visible by other techniques. The method has been discovered by K. B. MULLIS in 1983 [16], [17] and has revolutionized molecular biology. Since that time numerous applications of the PCR method were developed, reflected in the exponential increase in the number of publications. In 1993 K. B. MULLIS eventually received half of the Nobel Prize for Chemistry due to his epoch-making invention. PCR is simple to perform, fast, flexible and combines high specificity and high sensitivity in contrast to other detection methods where specificity and sensitivity are always incompatible. Due to its simplicity it has soon been introduced into many other fields, such as forensic science, diagnosis of genetic diseases, evolutionary biology, environmental science, food analysis, and so on.

[Top of Page]

3. Principle

The PCR reaction consists of three steps (equivalent to one cycle) which are repeated 25 to 35 times. During the first step template DNA is denatured (Figs. 1-3, step 1). Subsequently, two oligonucleotides (primers) anneal to complementary sequences of the single-stranded DNA (ssDNA) (Figs. 1-3, step 2). Primer sequences are then elongated by a thermostable DNA polymerase to recover double-stranded DNA (dsDNA) (Figs. 1-3, step 3). The products generated during the first and second cycle are of undefined length. Beginning with the third cycle amplicons with a defined length flanked by the two primers are produced (Figs. 1-3, white boxes). In the following cycles the number of defined amplicons increases exponentially whereas products of undefined length accumulate in a linear mode.

Figure 1. PCR principles — first cycle

Figure 2. PCR principles — second cycle

Figure 3. PCR principles — third cycle

The PCR temperature profile is shown in Figure 4. Denaturing of dsDNA is usually performed at 93 – 97 °C (step 1) for 15 to 60 s. Primer annealing temperature depends on the physicochemical properties of the oligonucleotides and ranges from 50 – 70 °C (step 2). Extension of primer sequences (step 3) by a thermostable DNA polymerase occurs at 72 °C for a few seconds to several minutes dependent on the length of the DNA fragment to be amplified. Because of the high temperatures, thermostability of polymerases is crucial for PCR reaction. In case of insufficient thermostability, enzyme (e.g., Klenow fragment ⟶ Enzymes) must be added for each cycle [18].

Figure 4. PCR temperature profile

The PCR reaction mixture contains reaction buffer (Section Reaction Buffer), two different primers (Section Primer), and a

thermostable DNA polymerase (Section DNA Polymerases) which needs magnesium chloride as cofactor and deoxynucleotides (dNTPs) (Section Deoxynucleoside Triphosphates (dNTPs)) as substrates. DNA or RNA may serve as template. RNA needs to be reverse transcribed to cDNA prior to PCR amplification.

Standard PCR. Because of the great number of parameters influencing the product yield it is impossible to specify conditions applicable to each PCR reaction. Nevertheless, parameters outlined below may be a starting point for optimizing PCR conditions.

The reaction volume may be chosen between 20 and 100 µL consisting of reaction buffer, primers (each 1 µM), DNA polymerase (0.2 to 1 U, i.e., International Units, ⟶ Enzymes – Definition of Units), $MgCl_2$ (1.5 mM) and dNTPs (100 – 200 µM each). A temperature profile of 94 °C for 30 s, 55 °C for 30 s and 72 °C for 1 min works in most cases. Usually 35 cycles are enough to visualize the PCR product on ethidium bromide stained agarose gels under UV illumination.

[Top of Page]

4. Reaction Components

4.1. DNA Polymerases (see also ⟶ Nucleic Acids – DNA Replication)

Since the introduction of PCR the number of thermostable DNA polymerases [19] has been increasing continuously. *Taq* DNA polymerase, the prototype of thermostable DNA polymerases had been isolated from the bacterium *Thermus aquaticus* in 1968 by BROCK [20]. Since that time many other thermostable DNA polymerases have been isolated (Table 1). Thermostable DNA polymerases can be differentiated by their nuclease activity, thermal stability, optimal reaction conditions, and their reading accuracy (fidelity). DNA polymerases having a 5′-3′ nuclease activity are capable of repairing DNA which has been damaged (e.g., by UV light, X-rays, or chemicals). Polymerases with a 3′-5′ nuclease activity are proofreading enzymes which recognize wrongly inserted nucleotides and replace them by right ones. Polymerases having both functions are those with the greatest fidelity and thus with the lowest error rate.

The concentration of the DNA polymerase varies between 1 and 5 U per 100 µL PCR reaction.

Table 1. Properties of various thermostable DNA polymerases

DNA polymerase	Source	Exonuclease activity		Half-life at 95 °C, min
		3′-5′	5′-3′	
Pwo	*Pyrococcus woesii*	yes	no	?
Taq	*Thermus aquaticus*	no	yes	40
Pfu	*Pyrococcus furiosus*	yes	yes	120
Vent	*Thermococcus litorales*	yes	no	400
Deep Vent	*Thermococcus litorales*	yes	no	1380
Tfl	*Thermus flavus*	no	no	?
Tth	*Thermus thermophilus*	yes	no	20
Ultma	*Thermotoga maritima*	yes	no	50

Application of a recombinant thermostable DNA polymerase combined with modified buffer composition and cycling conditions allow amplification of DNA fragments of up to 40 000 base pairs (bp) [21], [22]. Amplification of long fragments is designated as XL (extra long) PCR and the most widely used enzyme for this purpose is r*Tth* polymerase (recombinant *Thermus thermophilus* polymerase) [23], [24]. This polymerase requires magnesium acetate instead of $MgCl_2$ and the optimal extension temperature is 68 °C. Usually annealing and extension are carried out at the same temperature (68 °C). Template quality is decisive for successful XL PCR. Therefore, template DNA must be handled very carefully to avoid disruption.

4.1.1. *Fidelity*

The proportion of altered DNA molecules after PCR amplification *f* depends on the DNA polymerase error rate per cycle *p*, the number of cycles *n*, and the number of target molecules prior to PCR amplification s_0:

$$f = \frac{(s_0 \cdot p)(n \cdot 2^{n-1})}{s_0 \cdot 2^n} = \frac{n \cdot p}{2}$$

with $s_0 \cdot p$ being the error per cycle, and $n \cdot 2^{n-1}$ the increase in DNA molecules during the PCR process. For example, the error frequency of an enzyme with an error rate of 1×10^{-4} amounts to 0.1 % after 20 cycles of amplification, which equals one error per 1000 nucleotides. Under the same conditions a polymerase with an error rate of 5×10^{-6} produces only five errors in 200 000 nucleotides which is one error per 40 000 nucleotides. Accordingly, error frequency can be reduced simply by decreasing the number of cycles and/or using a polymerase with both, 5′-3′ and 3′-5′ exonuclease activity, i.e., a high fidelity. This is especially important when PCR products are to be cloned.

4.1.2. *Mg^{2+} as Cofactor*

Mg^{2+} is a cofactor of almost all DNA polymerases with an optimal concentration between 1.0 and 5.0 mM. A high Mg^{2+} concentration causes formation of unspecific products and a low amount of Mg^{2+} ions results in little or no PCR product. The Mg^{2+} concentration needs to be optimized for each PCR reaction.

4.1.3. *Inhibitors*

Numerous substances (Table 2) are known to inhibit processivity of DNA polymerases [25]. Such inhibitors are often contained in sample materials and may be copurified with template DNA.

However, it has also been demonstrated that the sensitivity of various DNA polymerases to inhibitors present in samples is different [26]. For example, when r*Tth* was used instead of *Taq* DNA polymerase it became possible to amplify DNA in the presence of 20 vol % blood without reduced amplification sensitivity, whereas *Taq* DNA polymerase was totally inhibited in the presence of 0.004 vol % blood in the PCR mixture.

Most frequently DNA is isolated from blood which contains EDTA or heparin to prevent coagulation. Both substances inhibit DNA polymerases. Therefore, it is important that blood samples are not preserved with coagulation inhibitors. Porphyrin compounds in the blood itself are also known to prevent amplification. This is the reason why cells (leukocytes, bacteria, yeast, etc.) must be separated from erythrocytes to eliminate porphyrin compounds. Meanwhile, DNA extraction kits are commercially available (e.g., Qiagen, BioRad) which are not only to be used for DNA extraction from blood samples but also from tissue, bacteria, viruses, etc.

DNA prepared by phenol/chloroform extraction must be free of traces of phenol and sodium dodecyl sulfate (SDS) since both inhibit DNA polymerases. Phenol can be removed by ethanol precipitation of DNA. Many DNA extraction methods are based on proteinase K treatment to lyse cells or bacteria. Since proteinase K hydrolyzes proteins the enzyme must be removed or inactivated because otherwise it would destroy the DNA polymerase. Heating of the suspension for 10 min to 100 °C inactivates proteinase K.

Table 2. PCR inhibitors

Substance	Concentration
Sodium docecyl sulfate (SDS)	> 0.005 wt %
Phenol	> 0.2 vol %
Ethanol	> 1 vol %
Isopropanol	> 1 vol %
Sodium acetate	≥ 5 mM
Sodium chloride	≥ 25 mM
EDTA	≥ 0.5 mM
Hemoglobin	≥ 1 mg/mL
Heparin	≥ 0.15 U/mL
Urea	> 20 mM

Samples being suspected of containing inhibitors should be treated in one of the following ways:

1. *Dilution:*
   Dilution of samples decreases the inhibitor concentration in the sample and thus enables amplification. Because dilution of samples is coupled with a loss in PCR sensitivity this technique should be used only when a sufficient amount of DNA in the samples is to be expected.
2. *Precultivation of bacterial samples:*
   Since PCR amplifies not only DNA from living but also from dead bacteria the message of PCR results has to be evaluated. If only living bacteria are to be detected a precultivation step is indispensable. By this way inhibitors are diluted and the amount of template DNA is increased. Thus PCR sensitivity is also increased, but the additional step involves the danger of contamination.
3. *Nested PCR (see also Section Increasing Sensitivity):*
   If there is some remaining activity of the DNA polymerase after the PCR or if new polymerase is added, two consecutive PCRs may be performed. Products from the first round of PCR are reamplified in a second PCR with primers directed against an internal region of the PCR product. Since only a small volume of the first PCR reaction is added to the second PCR, inhibitors are diluted.
4. *DNA extraction:*
   In most cases inhibitors are removed by DNA extraction. These methods are described in Section Extraction of Template DNA.

4.2. Deoxynucleoside Triphosphates (dNTPs)

Deoxynucleotides (dATP, dCTP, dGTP, dTTP) are used in final concentrations (f.c.) of 50 – 200 µM each. Higher concentrations may cause errors of the DNA polymerase. If lyophilized powder of dNTPs is to be used, the solution must be neutralized to avoid degradation of the nucleotides. It is more convenient to use ready-to-use dNTP mixes which are commercially available from many suppliers (e.g., Carl Roth, Biozym, Applied Biosystems, MWG Biotech). One point

should be kept in mind when varying dNTP concentration: Mg^{2+} is bound quantitatively by dNTPs, therefore the amount of Mg^{2+} ions has to be adjusted whenever changing the dNTP concentration.

4.3. Reaction Buffer

In general, PCR buffer consists of 10 mM *N*-Tris(hydroxymethyl)aminomethane (Tris), pH 8.4, 50 mM KCl, 0.01 % gelatin, and nonionic detergents. Nonionic detergents (NP-40, Tween 20, both in a concentration of 0.1 vol %) are needed to achieve maximum processivity of the DNA polymerase. Reaction buffer as well as $MgCl_2$ are supplied together with the DNA polymerase by the manufacturer.

4.4. Primer

4.4.1. *Melting Temperature*

According to definition the melting temperature T_m is the temperature where 50 % of the DNA molecules are double-stranded and 50 % are single-stranded. The T_m depends on the guanosine – cytosine (G – C) content of the DNA, the salt and the primer concentration. If the G – C content of the primers is nearly 50 % T_m may be approximated by the following equation:

$$T_m = 2 \cdot (\text{no. A and T}) + 4 \cdot (\text{no. G and C})$$

For example, the oligonucleotide 5′-AGC TGC CTA GAT CGA GTA CGT TGC-3′ is composed of 11 As and Ts and 13 Gs and Cs, thus the T_m can be calculated as:

$$T_m = 2 \cdot 11 + 4 \cdot 13 = 64^\circ\text{C}.$$

The melting temperature (T_m) is calculated automatically if using commercially available primer design software packages.

4.4.2. *Concentration*

In most cases primers are delivered as lyophilized powder. Although the enclosed primer data sheet includes the mass of the primers it is good practice to determine the concentration of primers after dissolving in an appropriate solvent (e.g., bidistilled water or 10 mM Tris/1 mM EDTA). The primer concentration of this solution can be calculated from the optical density (OD) at 260 nm. For primers with a G – C content around 50 % the following equation can be applied [27]:

$$c_{\text{Primer}} = \text{OD}_{260} \cdot 33[\text{ng}/\mu\text{L}] \text{ or}$$

$$c_{\text{Primer}} = \text{OD}_{260} \cdot 100/n[\text{pmol}/\mu\text{L}]$$

where *n* is the number of bases.

4.4.3. *Synthesis*

Oligonucleotides are synthesized fully automatically on a solid phase support. The solid phase consists either of controlled pore glass (CPG) or polystyrene particles, which are already loaded with the first base to be synthesized. Consequently, there are A, G, C, and T columns. Synthesis starts at the 3′ end of the primer. During synthesis modified bases may be incorporated, e.g., fluorophores, biotin or digoxigenin labeled bases, inosine, etc. If primers are to be constructed from protein sequences inosine is the base of choice for the wobble positions in a codon. Inosine may be incorporated by polymerases into growing dsDNA opposite each of the four bases (A, G, C, or T). Such oligonucleotides are designated as “degenerated”. DNA synthesis services are offered from many companies (e.g., MWG Biotech, Carl Roth, Applied Biosystems) in different scales (0.01 – 10 µmol).

4.4.4. *Primer Design*

A precondition for successful establishment of a PCR is the choice of convenient primers. Many primer design software programs are now available which allow to set appropriate options and to seek for compatible primer pairs automatically. Basically, there are four different ways to obtain primer sequences or sequences from which primers are to be deduced:

1. From literature
2. From database entries
3. From newly obtained sequences in the course of a sequencing project, and
4. From protein sequences

Basic conditions for the primers to be fulfilled are: high specificity and efficient annealing to the sequence of interest. This is especially important if there is only a minute amount of DNA to be amplified out of a high background of foreign DNA. The following parameters should be taken into consideration to design compatible primers:

1. A balanced base distribution
2. No stretches (more than 4) of bases and/or no repetitive sequence motifs
3. No stable secondary structures (self complementarities) especially at the 3′ end
4. No complementary sequences between primers (primer dimer formation), especially at the 3′ end
5. 15 – 30 bases in size
6. Final concentration 0.05 – 1 µM
7. Unique sequence
8. A maximum of 1 – 2 Gs and/or Cs at the 3′ end

9. T_m of both primers should be similar (± 2 °C), and
10. The size of the PCR product should be in the range of 100 – 600 bp.

The length of the primers can vary between 15 and 30 bases though most of them have sizes of 20 ± 2 bases. The standard concentration of primers is 1 µM. Only in special cases, e.g., when unspecific products are produced, specificity can be increased by decreasing the primer concentration.

Software. Primer design software may be ordered, e.g., from the following suppliers:

1. Medprobe AS, Oslo, Norway,
2. Molecular Biology Insights, Cascade, USA,
3. Scientific & Educational Software, Cary, USA,
4. Premier Biosoft International, Palo Alto, USA.

There are numerous freeware software programs available online which may be downloaded from the following URLs:

http://www.biocenter.helsinki.fi/bi/Programs/download.htm (FastPCR)

http://www.rsbs.anu.edu.au/Products&Services/BiotechnologyTransferUnit/gprime.asp (Gprime)

http://perlprimer.sourceforge.net/download.html (Perlprimer)

http://www.charite.de/bioinf/tgge/ (TGGE-Star)

Furthermore, primers can also be designed online under the following URL:

Autoprime:	http://www.autoprime.de/
Amplify:	http://bip.weizmann.ac.il/mb/bioguide/pcr/PCRsofAmplify.html
Codeshop:	http://blocks.fhcrc.org/blocks/codehop.html

Oligo2002:	http://www.bioinformatics.vg/bioinformatics_tools/oligo2002.shtml
Webprimer:	http://seq.yeastgenome.org/cgi-bin/web-primer

Primo is a package of programs allowing to design primers for many different applications, e.g., Standard PCR, Multiplex PCR, degenerate PCR, gene synthesis, RAPD.

4.5. Template

PCR may be performed with dsDNA, ssDNA, or RNA as template. The DNA fragment which is to be amplified must be deduced from a genetically stable region to obtain consistent PCR results. If possible, abundant DNA regions like repetitive DNA elements, rDNA regions, multicopy genes, or mitochondrial DNA should be chosen. In this way the sensitivity of the PCR reaction can be increased, since one template molecule contains several copies of the target DNA. This is especially true for PCR reactions where minute amounts of template DNA are expected.

If the total length of the genome *L* in base pairs and the DNA concentration is known, the number of molecules *n* in the PCR reaction prior to amplification can be calculated:

$$n = \frac{m \cdot 10^{12}}{1.1 \cdot L}$$

with *m* being the DNA amount in nanograms.

The PCR detection limit depends strongly on the material from which DNA has to be amplified. In the most extreme case the detection limit is one target molecule per PCR reaction. As a rule of thumb the volume of an unknown DNA-containing sample (e.g., clinical samples) should be no more than 1/10 of the total PCR reaction volume.

[Top of Page]

5. Equipment and Laboratory Preconditions

Reaction tubes (*PCR cups*) for DNA amplification are usually characterized by small size and thin walls for fast

temperature transduction. Exact pipetting of smallest amounts (0.2 – 1 µL) is crucial for PCR. Thus *micropipettors* for PCR must be of highest reliability.

Thermocycler. Soon after its discovery the PCR process was automated by using two approaches: robotics and temperature cycling devices. Most current cyclers are of the latter type. In robotics the temperature control stations are stationary and the samples are moved between these stations (Stratagene, robocycler), whereas in the temperature cycling devices the samples remain in the same physical position while sample block temperature is cycled under software control.

Due to the enormous progress in durability of Peltier elements almost all cycler types are based on this technique. Nevertheless, differences in ramp times for heating and cooling make it difficult to transfer cycle parameters from one model to another model of cycler. Mostly the cycle parameters need to be adapted. A heatable cover lid is a must for currently employed cyclers making it possible to omit overlaying the PCR reaction with mineral oil.

If the cycler is to be used in routine diagnostics with a high throughput of samples the cycler should have a high capacity (96, 384 wells) and accept microtiter plates. Cycler with several temperature blocks are advantageous if PCRs with different cycle parameters are to be used at the same time or if PCR parameters need to be optimized. Table 3 lists thermal cyclers with their corresponding features.

Table 3. Thermal cycler models

Supplier	Name	Capacity, cups per block	Special features	Real-time detection
Stratagene	Robocycler	40/96	Robotics	no
Biometra	-TGradient	48/96/384	gradient capability, slide cycling option	no
	Tpersonal	20/48		no
	T1	48/96/348	slide cycling option	no
Bio-Rad	MJ Mini Cycler	48	gradient capability	no
	PTC 100	60/96		no
	DNA Engine family	30/48/60/96/384	swappable alpha-units (blocks), slide cycling options, optional motorized lid	optional (Chromo 4 alpha unit), 4 channels
	Opticon 2	96	gradient capability	yes, 2 channels
	MiniOpticon	48	gradient capability	yes, 2 channels
	iQ5	96	gradient capability	yes, 5 channels
	MyiQ	96	gradient capability	yes, 1 channel
Eppendorf	Mastercycler			
	personal	25/16	1 universal block for 0.2 and 0.5 mL tubes, personal card	no
	gradient	96/77	1 universal block for 0.2 and 0.5 mL tubes, personal card, gradient capability	no
	Realplex 2, Realplex 4	96	gradient capability	yes, 2/4 channels
Applied Biosystems	2720	96		no
	GeneAmp 9700	60/96/384	interchangeable blocks	no
	7300	96		yes, 4 channels
	7500	96	fast version available (PCR in less than 40 min)	yes, 5 channels
	7900HT	96/384	PCR in less than 40 min, continuous wavelength detection from 500 – 660 nm	yes
Roche Diagnostics	Lightcycler			
	480	96/384	PCR in less than 40 min (384 block) and 1 h (96 block),	yes, 6 channels

			respectively	
	1.5/2.0	32	PCR in 20 min	yes, 3/6 channels
LTF-Labortechnik	Rotor-Gene	32/72/100	open system adaptable to all real-time techniques and dyes, spinning of samples at 500 rpm therefore no temperature variation from sample to sample	yes, 6 channels

PCR in a Diagnostic Laboratory. To perform PCR, including sample preparation, analysis and documentation at least three separate rooms or compartments should be available.

Room no. 1 is used to prepare PCR reagents and the PCR reaction mix (mastermix without DNA). For pipetting, weighing and measuring of chemicals only unused, non-autoclaved plastic ware should be used. The usage of these chemicals should be restricted to this single purpose.

In room no. 2 samples are received, prepared, and PCR reactions loaded with sample DNA. It is convenient to prepare samples in a laminar flow work bench with an integrated UV light source. All preparation steps should be carried out with sealed pipette tips to avoid contamination of the pipettor shaft with template DNA.

In room no. 3 amplification, electrophoresis, and documentation of PCR results take place.

There should be no direct connection between rooms and no air circulation from post-PCR to pre-PCR rooms. Access to these rooms should be restricted. Equipment should remain in the respective rooms and not moved between rooms. For each room separate protective clothing should exist and gloves have to be changed regularly.

[Top of Page]

6. Cycling Conditions and Reaction Phases

6.1. Denaturation Conditions

Complete denaturation of template DNA is necessary to achieve a high amplification efficiency. Typical parameters for denaturation are 93 to 95 °C for 15 to 30 s. If the template DNA has a high G – C content (> 60 %) denaturing time should be prolonged to 1 min or a pre-PCR denaturation step of 5 min should be performed. Denaturation time depends also on the PCR cups which are used. In general, only thin-walled PCR cups should be used to minimize temperature transition time from the heating block to the interior of the PCR cup.

6.2. Annealing Conditions

Annealing temperature and time depend on the base composition, the size and concentration of primers (Section Primer). These parameters have to be optimized for each PCR to achieve a high PCR product yield without unspecific side products.

6.3. Extension Conditions

Normally, the optimal extension temperature for the DNA polymerase is known. Activity of most thermostable polymerases is optimal at about 72 °C. Extension time depends on the size and concentration of the amplicon and is different for each DNA polymerase. For example, *Taq* DNA polymerase has a temperature optimum of 72 °C and a processivity at this temperature of 35 to 100 nucleotides per second. Thus, an extension time of 1 min would be enough to synthesize a DNA fragment of 2000 bases in size. However, since the amount of DNA increases with time and after a few cycles exceeds enzyme concentration (about 1 nM) extension time has to be adapted. A starting point for optimization extension time should be 10 s per 100 base pairs.

6.4. Amplification Phases

From a certain cycle on exponential amplification of the DNA template switches to a linear and finally to a stationary phase. The stationary phase is designated as “plateau”. The plateau effect can have the following reasons:

1. Consumption of substrates (dNTPs and/or primers),
2. Inactivation of the DNA polymerases and/or the dNTPs,
3. Inhibition of the DNA polymerase by excess of dsDNA and pyrophosphates,
4. Competition by unspecific products or primer dimers,
5. Reassociation of specific products at concentrations above 10^{-8} M, and
6. Incomplete denaturation of the specific product at high product concentrations

The plateau effect can be avoided by decreasing the DNA amount before amplification and/or by reduction of the cycle numbers. In most cases the amount of PCR product is sufficient for downstream manipulations (gel electrophoresis Section Gel Electrophoresis, restriction analysis Section Restriction Analysis, sequencing Section Sequencing, etc.).

[Top of Page]

7. Characterization of PCR Products

7.1. Gel Electrophoresis

Electrophoresis of DNA is performed on agarose or polyacrylamide gels. In electric fields DNA molecules migrate to the positive electrode due to their negatively charged surface. Migration of molecules depends only on the size if the molecules are equally charged. Hence, length of DNA fragments may be determined by gel electrophoresis.

7.2. Restriction Analysis

Endonucleases type II restrict double-stranded DNA at specific restriction sites consisting of characteristic base sequences so that sticky or blunt ends of DNA are generated. Restriction of amplicons results in DNA fragments of characteristic and previously determined length if the DNA sequence of template DNA is known (Fig. 5).

Figure 5. Restriction analysis of different PCR products (1, 2, and 3). Amplicons in lanes 1A, 2A, and 3A have been restricted with *Not*I generating two fragments in each case (1B, 2B, and 3B).

M = molecular mass marker

7.3. Hybridization

For identification of DNA fragments, i.e., amplicons, hybridization techniques are considered to be very reliable tools. During hybridization double-stranded DNA is generated from complementary strands with different origin. The sequence of one strand is known and thus binding allows conclusions to be drawn about the sequence of the other strand. The molecule with known sequence is labeled and designated as probe. Prior to hybridization amplified DNA (eventually after electrophoresis) is transferred to membranes where hybridization is carried out [28].

7.4. Sequencing

Nowadays DNA sequencing is mainly carried out automatically based on cycle sequencing principles [29] with labeled dideoxynucleotides as chain-terminating component [30], [31].

[Top of Page]

8. Modifications of PCR for Increased Specificity and Sensitivity

8.1. Increasing Specificity

Apart from optimizing $MgCl_2$, polymerase (Section Mg^{2+} as Cofactor), or primer concentration (Section Concentration) further techniques exist for increasing specificity of PCR.

If very small amounts of DNA (i.e., 100 templates or less) are contained in the sample, in the first few cycles nucleotides, primers, and DNA polymerase are present in a great excess and therefore the probability that unspecific products or primer dimers are formed is very high. In this case it is advisable to change the PCR technique and use techniques like Booster, Hot Start, and Touch Down PCR.

With currently available thermocyclers it is possible to check annealing temperatures for maximum specificity within one PCR run. This is achieved by thermocycler blocks allowing to generate a temperature gradient over the block cavities (Thermal cycler with gradient capability, Table 3). Such an approach is especially important for institutions which must establish a great number of different PCR methods or which must perform different PCR assays with primer pairs having incompatible annealing temperatures.

Booster PCR. In Booster PCR the primer concentration at the very beginning of amplification is very low and additional primers are added after a few rounds of amplification. However, this technique is used very rarely since the PCR cup has to be opened for a second time and thus the risk of contamination increases.

Hot Start PCR. In Hot Start PCR two compartments are formed which are separated by a wax layer. The lower compartment contains PCR buffer, $MgCl_2$, nucleotides, and primers and the upper compartment contains PCR buffer, DNA polymerase, and template DNA. When the cycling process starts the wax layer is liquefied, the two compartments are merged and amplification is initialized.

In the late 1990s DNA polymerases which do not exhibit any activity at room temperature were introduced (Applied Biosystems, Qiagen). Inactivity at ambient temperatures is achieved by a chemical modification of DNA polymerases or blocking of the enzyme with an antibody [32]. Activity is fully released only when the system is heated to 95 °C for several minutes. This kind of Hot Start PCR eliminates the need of separating PCR reagents by a wax layer, it is performed like a “normal” PCR reaction. As mentioned above, full activity of the DNA polymerase in early cycles of PCR is not necessary. Therefore, the activity of these enzymes may be only partially released by decreasing the retention time at 95 °C. In subsequent cycles the remaining activity is released stepwise and thus the half-life of the polymerase can be increased so that PCRs with up to 60 cycles can be performed. Thereby, not only specificity but also sensitivity of the PCR reaction is improved [33].

Touch Down PCR. In Touch Down PCR the first 5 to 10 cycles are performed at annealing temperatures which are very stringent so that unspecific primer annealing is prevented. For example, in the first cycle primer annealing is performed at 67 °C and subsequently annealing temperature is decreased by steps of 2 °C per cycle until the optimal annealing temperature of 57 °C is reached. The remaining cycles are performed at 57 °C.

8.2. Increasing Sensitivity

Although PCR is characterized in general by high sensitivity and specificity compared to other detection methods, modifications increasing PCR sensitivity may reduce specificity at the same time (cycling conditions, concentration of reagents) except for Nested PCR. Basically, sensitivity is increased by augmented $MgCl_2$ or high primer and polymerase concentrations while specificity is decreased.

Nested PCR technique is widely established for high sensitivity PCR with simultaneously increased specificity. The technique usually includes two primer pairs that are applied in two consecutive cycling reactions. During the first round a relatively large amplicon is produced with the first primer pair. This PCR may be of very low efficiency so that the PCR product can not be detected by electrophoresis. However, even small volumes of the reaction mix contain a great number of DNA molecules after amplification. These PCR products are then added as template to the second PCR. The second primer pair matches to an internal region of the amplicon and larger amounts of a second smaller PCR product are generated.

Nested PCR. Nested PCR technique is on the one hand used for avoiding effects of polymerase inhibitors (Section Inhibitors) but also for enhancing sensitivity. As an additional effect specificity is also increased, since the second primer pair would not match to unspecific amplicons from the first round but solely to specific PCR products with complementary sequences. Beside these positive effects, extreme sensitivity also means increased risk of false positive reactions due to minute contaminations.

Whole genome amplification (WGA). WGA is an in vitro procedure to amplify whole genomic DNA from trace quantities of starting material. This procedure is a tool applied in many fields (genetic analysis, linkage studies, pharmacogenetics, human disease research) and is especially valuable in cases where only limited amounts of precious material are available.

PCR-based and non-PCR-based techniques were developed to amplify whole genomes. PCR-based methods include degenerate oligonucleotide primed-PCR (DOP-PCR) and primer extension PCR (PEP). Non-PCR-based methods are multiple displacement amplification WGA (MDA WGA) and T7-based linear amplification (TLAD).

DOP-PCR uses a partially degenerate oligonucleotide primer that binds during several low-temperature annealing cycles at many sites in the genome (approximately 10^6 sites in humans). This preamplification step is followed by PCR amplification at a higher temperature to allow only those initial fragments that are tagged with the specific part of the primer sequence to be amplified.

PEP uses a 15 base random oligonucleotide primer which anneals at a low stringency temperature (37°C) to its target. Subsequently the annealing temperature is gradually ramped (10 s/°C) up to 55°C prior to a 4 min elongation step (55°C). Using this technique approximately 78% of the genome from a single haploid cell can be copied at least 30 times during 50 cycles of amplification.

MDA WGA is based on the unique property of Phi29 DNA polymerase to replicate linear genomic DNAs by strand displacement amplification. The reaction uses random hexamers as primers for DNA synthesis and is performed routinely overnight at 30°C. This powerful technology allows up to 1000-fold amplification of starting material.

The first step in the TLAD protocol implies digestion of genomic DNA with the restriction endonuclease AluI. Terminal transferase is then used to add polyT tails to the 3'-ends of the digested DNA strands. An oligonucleotide primer, containing a 5' T7 promoter and a 3' polyA tract, is annealed to the genomic fragments, and Klenow is used for synthesis of the second strand. The reaction products of this synthesis are then used as templates for the in vitro transcription reaction.

PCR-based methods are generally more amenable to non-specific amplification artifacts and an incomplete coverage of loci (allelic bias). PCR products have a mean length of about 3 kb (kilobase pairs).

One of the major advantages of non-PCR-based methods is that they do not introduce the sequence- and length-dependent biases observed in PCR-based amplification. Amplification products generated with isothermal methods are about 10 kb in length.

[Top of Page]

9. Contamination

9.1. Sources of Contamination

Since PCR is the most sensitive method so far for DNA/RNA detection even minute contamination of reagents, PCR cups, pipette tips etc., with template DNA may be the reason for false positive PCR results. Amplicons are the most probable source for contamination of PCR reactions. For example, if the product yield after PCR is about 1 µg, a droplet volume of 1 pL (10^{-12} L) would be enough to contaminate a PCR reaction with 1×10^5 amplicon molecules assuming an amplicon size of 500 bp.

Furthermore, samples containing DNA templates to be detected may be a source of contamination. Therefore, PCR cups should be closed as soon as sample DNA is added to the PCR reaction. To be on the safe side, samples as well as positive and negative controls should be amplified in duplicate or even in triplicate.

Depending on the kind and properties of the template particular precautions have to be taken. Samples which are to be examined for human sequences must be considered as especially problematic since template DNA is ubiquitous, e.g., as hair and/or skin cells, as human cells on surfaces or even in the air. Also bacteria that are commensals on the human skin

(*Staphylococcus* spp., *Streptococcus.* spp., *Mycobacteria* spp.) require special measures.

9.2. PCR Controls

To avoid false-negative and/or false-positive results controls have to be included. Faulty PCR reactions which would provide a false-negative result can be avoided by *positive controls*. For this purpose the PCR reaction is deliberately contaminated with template DNA. Thus the PCR result must be positive at least for this control reaction otherwise the whole reaction has to be repeated. If inhibitors in the sample are causative for negative results, there are two possibilities to demonstrate this particular problem: (1) add the DNA to be amplified to the sample or (2) add an internal control to the sample.

In both cases the PCR result must be positive if inhibitors do not interfere. In case (2) the internal control must be chosen in such a way that the amplicon sites of internal control and the actual amplicon are different in size. Internal controls can be added to each sample. Thus three different PCR results are possible:

1. Internal control and actual amplicon positive — conclusion: sample positive,
2. Internal control positive, actual amplicon negative — conclusion: sample negative,
3. Internal control and actual amplicon negative — conclusion: sample contains inhibitors

False positive results can be avoided by including *negative controls*. To test PCR reagents for contaminations with template DNA bidistilled water is added to the PCR reaction instead of template DNA. In this case the PCR result has to be negative.

Detection of pathogens in, e.g., blood requires blood samples as negative controls which do not contain the template DNA. Subsequently for DNA preparation from blood samples the negative control is prepared in exactly the same way as regular samples. After DNA preparation the PCR result of this negative control must be negative otherwise the reaction including the preparation of samples must be repeated. The same approach can be used in case of positive controls.

9.3. Decontamination Methods

9.3.1. *Uracil-N-Glycosylase (UNG)*

For this decontamination method dUTP is substituted for dTTP in the PCR reaction. Since affinity of most of the DNA polymerases is similar for both dUTP and dTTP, dUTP is incorporated into the newly synthesized DNA strand during PCR reaction. Thus prior to PCR amplification contaminations by amplicons from previous PCRs can be removed by addition of UNG (AmpErase) to the PCR reaction and incubation of this mixture at 37 °C. UNG catalyzes hydrolysis of uracil-containing nucleic acids and thus destroys uracil-containing amplicons without affecting original template DNA. After hydrolysis UNG is inactivated automatically at the PCR cycle conditions.

This method can be varied in such a way that the PCR primers are synthesized with dUTP instead of dTTP. Such primers are designated as *amplimers*. This modification has the advantage that PCR reactions can be performed with the natural substrate dTTP. Nevertheless, contaminating amplicons are marked by dUTP and hence destroyed by UNG.

Decontamination of PCR reactions by UNG is characterized by the following properties:

1. Efficient inactivation of more than 10^6 template molecules (dsDNA or ssDNA),
2. Efficiency of PCR is not affected,
3. Post-PCR hybridization is not influenced,
4. No additional equipment is necessary, and
5. The PCR product can be sequenced and cloned regularly

However, the following PCR manipulations of the amplicon are not possible:

1. dUTP does not serve as substrate for endonucleases
2. Only G – C parts of amplicon sequence can be used in restriction analysis
3. Protein – DNA interaction studies may be impaired

9.3.2. *UV Light*

Contaminating DNA in PCR cups and reagent components except sample DNA, primers, and DNA polymerases can be removed by UV irradiation. In this context several properties not only of the DNA but also of the UV light have to be taken into consideration:

1. Pyrimidine base content of the DNA, especially thymidine content,
2. Size of the DNA,
3. Irradiation time,
4. Distance from the UV source,
5. Wavelength of the UV light, and
6. Energy of the UV light

A transilluminator may be used as UV source but to obtain reproducible results, items 3 to 6 need to be controlled. Several UV sources (UV cross-linkers) are available which allow exact control of these items (Amersham, Stratagene). To achieve effective decontamination, PCR cups and solutions should be treated for more than 10 min at 254 nm wavelength and with a power of 100 µJ/min.

9.3.3. *Enzymes*

In cases where other methods are inappropriate, DNA modifying enzymes like DNAse I, exonuclease III and restriction enzymes may be used for decontamination. If for example solutions (e.g., media) are to be used which are not specified as DNA free and which are sensitive to other decontamination methods mentioned above, enzymes can be applied to "sterilize" these solutions. Subsequently, added enzymes are inactivated by heating solutions to 100 °C for 10 min or by autoclaving.

9.3.4. *Psoralens and Isopsoralens*

Prior to PCR contaminating DNA can be "inactivated" by *psoralens* (natural furocoumarins, e.g., 8-methoxypsoralen) which irreversibly cross-links both DNA strands during irradiation with UV light (wavelength 300 – 400 nm). By linking of both strands denaturing of DNA and thus amplification is no longer possible. Psoralens are added to PCR reactions (without sample DNA) and contaminating DNA is "inactivated".

Isopsoralens (4-aminomethyl-4,5-dimethylisopsoralen and 6-aminomethyl-4,5-dimethylisopsoralen) form DNA-monoadducts upon exposure to long-wave UV light. Such modified DNA is no longer recognized as substrate by DNA polymerases. Isopsoralens are added to the PCR reaction prior to amplification but irradiation with UV light is performed after amplification so that amplicons are inactivated at once.

[Top of Page]

10. Quantitative PCR

Soon after the development of PCR experiments were performed not only to qualify but also to quantify nucleic acids in samples. Applications of quantitative methods are numerous and include diagnostic testing as well as therapeutic monitoring for neoplastic or infectious diseases or analysis of gene expression (Section PCR for Analysis of Gene Expression) [34], [35].

Quantitative PCR is used to infer from amplified products to the number of template molecules prior to PCR. The relation between the initial number of molecules and amplified product is described by an exponential function:

$$y = a(1 + E)^n$$

with

y = product yield (amount of DNA after amplification)
a = amount of template DNA prior to PCR
E = efficiency of the amplification process
n = number of cycles

Logarithmic transformation of this equation results in an equation for a straight line:

$$\log\ y = \log\ a + n\ \log(1 + E)$$

with log *a* being the *y*-axis intercept and log (1 + *E*) the slope of the straight line. This equation can only be applied to the exponential phase of the PCR reaction which depends on the initial number of template molecules and the number of PCR cycles.

To quantitate template DNA, a standard control DNA with a known number of molecules has to be coamplified. Control DNA may be coamplified in a separate PCR cup (external control) or in the same PCR cup as the sample DNA (internal control).

10.1. External Control

External controls are amplified by subjecting different amounts of a known DNA to PCR to obtain a standard curve. The amount of sample DNA amplified in parallel can be derived directly by interpolation of the standard curve. Preconditions for this quantification method is that the efficiency of both PCRs, that of the control DNA and that of the sample DNA, is identical and that the amplification reaction is in the exponential phase.

10.2. Internal Control

PCRs using internal controls (IC) for quantification may be performed as multiplex or competitive PCR.

In *multiplex PCR* the primer pair for the IC is derived from a different DNA molecule than the primer pair for sample DNA whereas in *competitive PCR* the same primer pair is used for both, the IC and sample DNA. Preconditions for quantification by multiplex PCR are the same as for PCRs using external controls. The only advantage of multiplex PCR as compared to PCRs using external controls is that both IC DNA and sample DNA are amplified in the same tube and thus problems due to variations in tube consistency or position in the thermal cycler are eliminated.

Competitive PCR. In competitive PCR amplicons generated from the IC and sample DNA by the same primer pair have to be differentiated. This can be achieved by modification of IC DNA either by deletion or insertion of an internal sequence. If an internal region is deleted amplicons generated from the IC are smaller and if an internal region is inserted they are larger than amplicons from sample DNA. In competitive PCR both IC DNA and sample DNA compete for the same primer pair. If the amount of initial template DNAs (IC and sample DNA) is unequal, PCR product yield is shifted to the credit of the DNA being in excess. Only when the amount of initial template DNA is equimolar, product yield for IC and sample DNA is identical. Thus the amount of sample DNA prior to PCR can be directly calculated from the known amount of IC DNA

(Fig. 6). If PCR products have been labeled during amplification (e.g., by incorporation of radiolabeled nucleotides, fluorescent or chemiluminescent labeled primers) gels can be analyzed by densitometric methods. In contrast to the above-mentioned quantification methods, quantification by competitive PCR is independent of cycle number and thus independent from the amplification phase.

Figure 6. Schematic representation of competitive PCR for quantification of PCR products. Sample (upper bands) and internal control (lower bands) are amplified at different dilutions (lane A – K). Identical band intensities of sample and control DNA indicate identical starting copy numbers of template DNA in the sample and initial copy number of the internal control (lane F)

10.3. Real-Time Quantification

The breakthrough in PCR quantification was achieved by the development of systems making it possible to detect PCR products immediately during their formation in the reaction tubes. The fluorescence signal produced during PCR can be measured on-line in an integrated thermocycler by an automatic system for quantitative PCR. Meanwhile different systems are available for realtime quantitative PCR (Table 3).

Real-time quantification of PCR products is possible with fluorescent dyes binding to dsDNA. For this purpose Sybr Green I, which is highly sensitive and specific for dsDNA, is particularly suited. Its fluorescence is greatly enhanced by binding to dsDNA and the emitted signal is proportional to newly synthesized dsDNA.

10.3.1. *Fluorescence Resonance Energy Transfer (FRET)*

If more specific detection is required, adjacent hybridization probes can monitor the appearance of a specific product during the reaction. The probes are designed to be internal to the amplification primers. The 3′ end of the probe is labeled with a donor fluor while the 5′ end of an adjacent probe is labeled with an acceptor fluor. FRET will occur only when the two probes hybridize to the amplicon in close proximity. During FRET the donor fluorophore is excited by an external light source and emits light that is absorbed by a second acceptor fluorophore (Fig. 7). The acceptor fluorophore emits light of a different wave length that is filtered and measured. The amount of FRET signal is proportional to the amount of specific PCR product available for hybridization, thus the signal increases after each thermal cycle. The FRET principle for fluorescent PCR analysis on the LightCycler is called hybridization probes format.

Figure 7. Schematic representation of the Fluorescence Resonance Energy Transfer (FRET) principle. A donor fluorophore (F1) is excited by an external light source. Emitted light is absorbed by an acceptor fluorophore (F2), that is in close proximity. The acceptor fluorophore then emits light of a different wavelength that can be measured.

The LightCycler instrument (Roche Diagnostics) (Fig. 8) is a rapid thermal cycler combined with a microvolume fluorimeter utilizing high quality optics. This machine features rapid thermal cycling and flexible on-line, real-time detection of the reaction kinetics. Heating and cooling are controlled by alternating heated and ambient air as the medium for temperature transfer. Due to the low mass of this medium, very rapid temperature exchanges can be achieved within the thermal chamber. The LightCycler amplification technique uses durable glass capillaries as reaction vessels, placed in a sample carousel. Because of the high surface-area-to-volume ratio, capillaries are highly efficient at transferring heat, thus permitting rapid cycling. With the LightCycler 30 cycles can be performed in less than 30 min. Furthermore the glass capillary serves as an optical element for signal collection (similar to glass fiber optics), piping the light and concentrating the signal at the tip of the capillary. The effect is efficient illumination and fluorescence monitoring of the microvolume samples. The capillaries permit reaction volumes from 5 – 20 µL.

The fluorimeter, as part of the machine, houses the light source: a maintenance-free light emitting diode (LED). The emitted light from the diode is filtered and focused by an epi-illumination lens onto the capillary tip. Fluorescent light emitted from the sample is then focused by the same lens, passed through a dichroic mirror, filtered appropriately and focused on data collecting photoelectric cells. Data may be collected once per cycle or continuously for quantification of PCR products. For confirmation of specificity, data are collected stepwise after defined temperature intervals so as to monitor melting characteristics of the amplicon.

Figure 8. Principle of the LightCycler

10.3.2. *Förster Energy Transfer (TaqMan System)*

The 5′-3′-exonuclease activity of the *Taq* DNA polymerase may also be used to generate signals during PCR. For that purpose a probe labeled with two fluorescent dyes is added to the template DNA. The probe contains a reporter dye at the 5′ end and a quencher molecule at the 3′ end. The vicinity of the quencher molecule reduces the emitted fluorescence of the reporter dye by Förster energy transfer. During PCR the probe anneals to the denatured template DNA and is subsequently hydrolyzed through the 5′-3′ exonuclease activity of the polymerase. Thus reporter and quencher dye are separated from each other and the reporter signal increases (Fig. 9). Synthesis of the complementary strand is finished

subsequently. Since in each cycle reporter molecules are liberated, fluorescence increases proportional to the number of synthesized PCR products. For quantification of results the increase in reporter fluorescence is measured real-time during the whole PCR process. For qualitative aspects, an end point determination is performed. For application of techniques based on Förster′s energy transfer refined technical equipment has been developed.

Figure 9. Förster Energy Transfer (FET) principle. PCR containing two primers and one probe is performed. The probe is labeled by a reporter (R) and a quencher (Q) molecule and is phosphorylated at its 3′ end. Phosphorylation avoids strand elongation by the DNA polymerase. As long as reporter and quencher are in close proximity fluorescence of the reporter dye is quenched. As soon as the reporter-labeled nucleotide is removed by the 5′-3′ exonuclease activity of *Taq* DNA polymerase the quenching effect is neutralized and the fluorescence of the reporter dye can be emitted.

In the TaqMan system (Applied Biosystems) blue laser light is lead through 96 glass fibers to the sample position of the integrated thermal cycler for fluorescence excitation (Fig. 10). Emitted fluorescence is directed through the glass fibers over a spectrograph to a charge-coupled device (CCD) camera recording every few seconds an emission spectrum of each probe in the microtiter plate.

Figure 10. Principle of the TaqMan system

MUX = Multiplexer; CCD = charge-coupled device

Recording of spectra makes it possible to use a second TaqMan probe labeled with a different reporter dye for the qualitative or quantitative measurement of an internal control. The possibility to directly follow up the PCR process allows a novel method for quantification of nucleic acids. Different PCR reactions are characterized by the time to their first detection and not as usually by the amount of accumulated PCR product. The more starting material is subjected to PCR the earlier a significant increase in fluorescence is measured. The C_T value (threshold cycle) characterized by the number of cycles at which the fluorescent signal exceeds a fixed threshold serves as parameter to determine the number of template molecules prior to PCR. For different PCRs, standard curves have to be generated by plotting C_T values versus initial copy numbers (Fig. 11). Quantification of the copy number of an unknown sample is achieved by extrapolation based on such standard curves.

Figure 11. Typical curves obtained from the TaqMan system to detect C_T (threshold) values.

Since the whole reaction is monitored, the linear range of the C_T curve (C_T values versus initial copy numbers) is more than six orders of magnitude. Post-PCR handling of samples is omitted; thus sample throughput can be increased and the contamination risk is decreased dramatically. Automation of the quantification process simplifies many applications as there are quantification of pathogens or transcription analysis in fields like medical research or pharmaceutical development.

Detection of PCR products in closed reaction tubes without further manipulation of amplicons is not only advantageous in quantitative PCR but also in end point analysis (5′ nuclease assay) to detect pathogens in food or drinking water.

[Top of Page]

11. Applications

11.1. Detection of Pathogenic Agents

Diagnostic PCRs offer several advantages over classical diagnostic methods: in vitro cultivation and differentiation of pathogens are hazardous, time consuming, or impossible [36]. Additionally, cultivation is in some cases restricted to certain laboratories. Furthermore, samples may be too small or contaminated for cultivation and sometimes alternative serological methods do not exist. Altogether the use of nucleic acid amplification techniques within the medical microbiology laboratory is becoming more and more accepted [37-39] and there is an increasing number of commercially available PCR test kits (Table 4).

Table 4. Commercially available PCR test kits

Organisms	Test kits	Supplier
Campylobacter jejuni, Escherichia coli O157:H7, Listeria monocytogenes, Salmonella spp. enterica	TaqMan pathogen detection kits	Applied Biosystems

Human, animal, and plant identification	AmpFLSTR amplification kits, StockMarks animal genotyping kit, and TaqMan GMO detection and quantitation System	Applied Biosystems
Viruses: HIV-1, HBV, CMV, HPV	AMPLICOR and COBAS AMPLICOR tests	Roche Diagnostics
Bacteria: *Chlamydia trachomatis, Neissereia gonorrhoeae, Mycobacterium tuberculosis, Mycobacterium intracellulare, Mycobacterium avium*	AMPLICOR and COBAS AMPLICOR tests	Roche Diagnostics
Viruses, bacteria, fungi	Lightcycler reaseach kits	Roche Diagnostics

11.1.1. *Preconditions*

The most important precondition for PCR based detection of microbes is the knowledge of sufficient DNA or RNA sequence data for development of primers (Section Primer). PCR is not convenient for general screening due to its high specificity except for universal PCRs (Section Universal PCR) or multiplex PCR (Section Multiplex PCR).

Generally, PCR based detection of pathogenic agents relies on a two step procedure and applied techniques should be combined in a modular way:

1. Isolation of microbial DNA as template, and
2. Amplification of template DNA by PCR

11.1.2. *Extraction of Template DNA*

Methods for isolation of template DNA are numerous and may be divided into two groups: isolation of total DNA from samples and specific preparation of microbial DNA. Total DNA contains DNA of pathogens plus large amounts of host DNA, that may interfere during PCR. On the other hand total DNA may serve as template for different PCRs detecting various pathogens.

11.1.2.1. *Isolation of Total DNA*

Total DNA from clinical samples is extracted enzymatically or mechanically followed by purification and concentration steps. Preparation methods depend on the sample type and the composition of the expected pathogens' cell wall, respectively. For the detection of intracellular pathogens both, host and microbial cells, must be lysed for DNA extraction. Usually mechanical homogenization (grinding or ultrasound treatment) or differential centrifugation is combined with enzymatic incubation (proteinase K, lysozyme), osmotic cell lysis, or boiling for the extraction of DNA.

After cell lysis added enzymes must be inactivated by boiling or removed by phenol – chloroform extraction. In many cases liberated DNA can be directly subjected to PCR. Nevertheless, if inhibitors (Section Inhibitors) are to be expected or the amount of template DNA is too low DNA must be purified and separated from cell debris.

A widely applied procedure consists in selective adsorption of DNA to silica or glass particles in the presence of high concentrations of chaotropic agents (i.e., sodium iodide, sodium perchlorate, or guanidinium thiocyanate) [40-42]. Elution of DNA is achieved with low-salt solutions or water. Selective adsorption of DNA to silica matrices allows removal of PCR inhibitors (Section Inhibitors). For purification of large amounts of DNA diatomaceous cell walls (petrified cell walls of algae almost entirely consisting of silicon dioxide and larger than synthetic silica particles) are suitable, because insoluble complexes of DNA and silica are avoided [43]. However, commercial silica matrices and convenient buffer systems, including lysis buffer, are widely distributed (e.g., BioRad, Qiagen, Eppendorf).

11.1.2.2. *Isolation of Pathogen Specific DNA*

For this purpose three techniques are established:

1. Propagation of pathogen (mainly on agar plates) and lysis of single colonies,
2. Immunomagnetic separation (IMS), and
3. Separation of template DNA by paramagnetic beads coated with a template specific DNA probe

The first procedure is mainly used for pathogens that are easy to cultivate. In this case PCR is predominantly a tool for further classification and characterization (e.g., slowly growing fungi, toxigenic microbes) and need not be very sensitive.

Immunomagnetic separation (IMS) is based on paramagnetic beads coated with monoclonal antibodies to capture the pathogenic agent specifically. After incubation of samples with coated beads pathogen bearing beads may be separated

magnetically and hence isolated pathogens are lysed for extraction [44], [45].

Another method, similar to IMS, uses paramagnetic beads coated with oligonucleotide probes complementary to the expected template DNA sequence. Incubation of beads is carried out after lysis of sample materials, pathogen specific DNA is captured by the immobilized DNA probe and magnetically concentrated. Beads may be subjected to PCR without interfering amplification.

The predominant advantages of pathogen specific isolation of DNA are low copurification of PCR inhibitors and generally concentrating of template DNA. All three procedures are not adequate for detection of different pathogens or multiplex PCR.

11.1.3. *Amplification*

Purified DNA may then be subjected to PCR reaction mix. If necessary concentration of DNA is achieved by precipitation with ethanol or isopropanol. For amplification of bacterial, fungal, and protozoal DNA conventional PCR in tubes is normally applied. Even samples with DNA viruses may be treated accordingly. Only amplification of RNA virus sequences needs reverse transcription of RNA to cDNA prior to PCR, using a commercially available reverse transcriptase.

Just as polymerases reverse transcriptases need starter molecules to prime the reaction. Usually nucleotide random hexamers or primers are used and the reaction mix is incubated at 42 °C for 45 min. Reverse transcription followed by PCR is often designated RT-PCR, and several attempts have been made to combine both reverse transcription and amplification in one tube.

Tth polymerase, isolated from *Thermophilus thermophilus*, has been shown to exhibit reverse transcriptase activity in the presence of manganese ions and polymerase activity with Mg^{2+} ions as cofactors. This enzyme has become available as recombinant protein r*Tth* and as component of a commercially available RT-PCR kit (Applied Biosystems). In contrast to other reverse transcriptases with an optimal activity at 42 °C r*Tth* polymerase can be incubated at higher temperatures. This property is particularly important if RNA with marked secondary structure is to be transcribed.

Another possibility for one-step RT-PCR consists in applying viral reverse transcriptase and a Hot-Start DNA polymerase for amplification, since this polymerase may be temperature-activated continuously after reverse transcription. One-step RT-PCR kits are available from many suppliers, e.g. Applied Biosystems, Eppendorf, Invitrogen, Promega, Qiagen, and Stratagene.

11.1.4. *Multiplex PCR*

To reduce expense of time and money, different PCRs may be combined to one reaction designated multiplex PCR [46], [47]. Most important for developing multiplex PCRs is that incorporated primers have very similar physicochemical parameters. Furthermore, the size of amplicons should also be similar, otherwise small amplicons are produced in expense of larger ones. However, a commercial multiplex PCR kit (Qiagen) is available, which contains a unique PCR buffer thus making it possible to perform multiplex PCR without further optimization. Multiplex PCRs are mainly applied in the differentiation of species or subspecies (e.g., characterization of slowly growing fungal isolates in one step) for screening purposes (e.g., pathogens or genetic disorders causing the same clinical signs) [48], and for microsatellite analysis.

11.1.5. *In Situ PCR*

Since the earliest descriptions of PCR technologies, researchers proposed performing amplification reactions in situ in non-disrupted cells and tissues with subsequent detection of the amplicon at the site of origin. The technique of in situ PCR provides a tool to localize rare sequences of DNA or RNA within a heterogeneous population. In situ PCR is widely applied for the detection of pathogens or for histological purposes like tumor diagnostics or genetic disorders [49].

Different types of PCR amplification are possible and the general process is shown in Figure 12.

Figure 12. In-situ PCR. Cells or tissues are fixed on slides and lysed. PCR reagents are added and the reaction volume is sealed to avoid evaporation. After thermal cycling PCR products are visualized microscopically.

Basically, direct and indirect in situ PCR technologies exist. For direct in situ PCR incorporation of labels into the amplicon is characteristic, whereas in indirect methods the PCR product is not labeled. Such amplicons must be detected afterwards by in situ hybridization with a labeled probe. For direct labeling of amplicons either hapten-labeled nucleotides (biotin-11-dUTP, biotin-14-dATP, digoxigenin-11-dUTP, fluorescein-15-dATP, numbers are indicating the size of the spacer i.e., the number of CH_2 groups between hapten and nucleotide) or hapten-labeled primers are added to the reaction (⟶ Nucleic Acids – Synthesis of Modified Oligonucleotides). In general, direct methods are faster but less specific. Indirect procedures including additional hybridization steps reduce the problem of unspecific, visible reaction products and are therefore considered the method of choice by many researchers. In situ PCR may also be conducted with RNA as template including reverse transcription step.

Cell smears, cryostat or paraffin sections, whole mounts, cell suspensions or chromosome spreads are considered to be

suitable preparations for in situ amplification. Nevertheless, convenient preparation of samples is crucial for successful in situ PCR protocols. The main difficulty in preparation is that harsh treatment may destroy template DNA or RNA. All preparations are made on silane-coated glass slides. Samples must first be fixed and then cells must be permeabilized. Fixation slides may be immersed in 4 % paraformaldehyde, formalin, ethanol – acetic acid or other fixatives. Formalin-fixed and paraffin-embedded sections (e.g., archival material) must be carefully dewaxed before further preparation. The following pretreatment is necessary in order to achieve penetration of the PCR components into the cells and allow the target sequence to be accessed for amplification. Permeability of cells is achieved by incubation of slides in HCl – pepsin, trypsin, or proteinase K solutions. At the end of incubation, enzymes are destroyed by short boiling. Sometimes additional steps (DNase digestion, removal of endogenous enzymes, etc.) are required prior to PCR. Then the PCR reaction mix is added to the slides which are to be sealed by tight cover discs and clips (AmpliCover discs and AmpliCover clips by PE Biosystems). After assembly the slides are inserted into particular thermocycler blocks and cycling is performed with two or three temperature programs. After amplification, the tissue sections can be refixed (ethanol, paraformaldehyde) to prevent loss of amplified DNA. Finally direct microscopic investigation or hybridization are performed.

11.1.6. *Universal PCR*

Several attempts have been made to develop so-called universal PCRs, so as to detect every kind of pathogen by a singular PCR system. All these experimental systems are based on amplification of highly conserved genetic regions common to all pathogens. Amplification is usually combined with sequencing of PCR products in order to find characteristic differences between species. Widely used genes for this purpose are 16S rRNA genes [50-52] or spacer regions for the detection and differentiation of bacteria [50], [53], [54]. Other sets of universal primers are based on genes of cold-shock proteins [55] or ribosomal proteins [56].

11.1.7. *PCR Controls for Diagnostic Purposes*

Because of the importance and implications of diagnostic results for therapy, prognoses, or epidemiology each reaction step must be controlled thoroughly. False positive or false negative results are mainly caused by contamination and inhibitors, respectively. To avoid these, the control reactions described in Section PCR Controls should be carried out.

Although PCR is highly specific post-PCR analysis is required in diagnostics to confirm the correctness of amplicons. Restriction analysis (Section Restriction Analysis), hybridization with specific DNA probes (Section Hybridization) and sequencing of the amplicon (Section Sequencing) prove specificity. Hybridization for this purpose may be carried out as microplate-capture method, which increases the sensitivity of the procedure and allows semi-quantitative evaluation [57], [58]. Altogether, diagnostic PCR procedures including template preparation should not take more than 24 h.

11.2. Detection of Genetic Disorders or Cancerous Cells

PCR technologies allow precise identification and analysis of mutations resulting in genetic disorders or neoplastic diseases. Reliable diagnosis of such mutations is particularly important for persons suffering from genetic diseases and individuals carrying pathogenic alleles, for prenatal consulting or tumor diagnostics. Special attention must be paid to the reliability of PCR results. Furthermore, results must be interpreted in the correct clinical context [59]. To save time in diagnosis multiplex PCRs (Section Multiplex PCR) may be developed.

Due to its high sensitivity and specificity even small amounts of altered DNA can be detected by PCR which is of particular interest in tumor diagnostics. Especially ARMS procedures (Section Known Mutations) are suitable since mutated DNA can be amplified out of a high background of intact DNA. Generally, methods for detection of known and unknown disorders must be distinguished.

11.2.1. *Known Mutations*

11.2.1.1. *Amplification Refractory Mutation System (ARMS)*

In this procedure, DNA is amplified with two primer pairs in separate assays. The first primer pair contains one primer specific for the mutated allele: the mutation is part of the primer sequence. With this primer pair only mutated DNA is amplified. The second primer pair amplifies the unaffected allele. Examination of diploid DNA leads to four possible results:

1. Amplification only with primer pair 1: DNA only contains mutated alleles. The patient is homozygous for that mutation.
2. Amplification only with primer pair 2: DNA only contains unaffected allele. The patient is homozygous.
3. Amplification with both primer pairs: DNA contains both alleles. Patient is heterozygous.
4. Amplification only with primer pair 2, but symptoms in patient: another mutation is responsible for disease.

In the case of cancer patients the results look like those of above-mentioned heterozygous persons. Combined techniques based on quantitative PCR and ARMS have been developed [60]. ARMS has been applied for example in the prenatal diagnostics of hereditary diseases and in screening for cancer cells during or after cancer therapy.

11.2.1.2. *Allele-Specific Oligonucleotides (ASOs)*

Similar to confirmation procedures for PCR-based detection of microbes, in this method PCR is followed by hybridization. Allele-specific oligonucleotides are short, single-stranded oligonucleotide probes. Differences in nucleotide sequence may be as small as one base pair so that point mutations may be detected. ASO-tests are usually conducted as dot blots (⟶ Nucleic Acids – Hybridization Techniques for Nucleic Acid Detection) with allele-specific oligonucleotides as probes.

If several mutations are to be examined at once, different allele-specific oligonucleotide probes can be immobilized to membranes. Then hybridization is carried out as reverse dot blot with labeled amplicon.

11.2.1.3. *Introduction of Restriction Sites*

Mutations may also be detected by enzymatic restriction (Section Restriction Analysis) of amplicons. Either mutated DNA

together with a primer constitutes a new restriction site or the pathogen allele contains a modified restriction site. Amplified DNA of pathogen alleles is then restricted in a different manner compared to DNA of normal alleles which easily may be shown in electrophoresis. However, partial restriction of DNA may simulate heterozygous genotype of patients.

11.2.1.4. *Competitive PCR*

For this technique allele-specific labeled primers are chosen. During amplification amplicons of identical length for every allele are generated that may be distinguished by different primer labeling (i.e., fluorescence). Amplicons of homozygous patients show the original fluorescence of primers whereas amplicons of heterozygous individuals show mixed fluorescence.

11.2.1.5. *Primer Extension PCR (PEST)*

This method represents a modified ARMS procedure. To one primer pair complementary to the interesting DNA region a third primer is added that corresponds to mutated DNA. In homozygous individuals with unmodified alleles only one large amplicon is generated. In heterozygous or homozygous individuals with mutated DNA two different amplicons are generated (Fig. 13).

Figure 13. PEST PCR

A) DNA molecules consisting of genes of identical allelic type (indicated by red circles) are subjected to PCR with primers specific for the mutated (red circle) gene and two primers from conserved regions of the gene (blue and green rectangles). Two PCR products are generated, one from the two conserved primers (larger amplicon) and one from the mutation-specific primer and the conserved primer (smaller amplicon).

B) In the case of heterozygous DNA the same PCR result is obtained as in panel A.

C) With DNA containing the unmutated gene (yellow circles) only the larger PCR product with the two conserved primers is obtained. The mutation-specific primer does not match.

11.2.2. ***Unknown Mutations***

For analyzing unknown mutations electrophoretic characteristics of differing PCR products are used.

11.2.2.1. *Denaturing Gradient Gel Electrophoresis (DGGE)*

This method allows the separation of DNA molecules, i.e., PCR products, differing in as little as a single base pair. The differentiation is based on the melting properties or denaturation characteristics of DNA. Amplicons are therefore analyzed on gel matrices with increasing denaturant concentration (formamide, urea, temperature). Parallel and perpendicular DGGE are distinguished depending on the orientation of the denaturant gradient.

In non-denaturing gel electrophoresis amplicons derived from different alleles migrate as one band whereas in parallel DGGE two bands are visible. Perpendicular DGGE however results in characteristic sigmoidal curves (Fig. 14).

Figure 14. Perpendicular DGGE. Amplicons from mutant (green line) and wild type DNA (yellow line) are analyzed on a gel with horizontally increasing denaturant concentration (0 – 100 %). Electrophoresis is performed perpendicular to the gradient. At low denaturant concentrations dsDNA is maintained. At medium concentrations of denaturant both DNAs, mutant and wild type DNA are partially melted whereas wild type DNA melts at slightly lower denaturant concentrations than mutant DNA. At denaturant concentrations near 100 % mutant and wild type DNA are completely denatured to ssDNA.

11.2.2.2. *Single Strand Conformation Polymorphism (SSCP)*

Differences in single-stranded DNA of up to 400 bp in length may be detected during electrophoresis. For comparison of putative DNA alterations PCR products are restricted, denatured, and separated electrophoretically as single-stranded DNA.

11.2.2.3. *Chemical Cleavage of Mismatches (CCM)*

Amplified DNA from altered alleles and labeled amplicons of normal alleles are mixed and denatured. During denaturation so-called heteroduplex DNA is generated that contains one marked strand derived from normal DNA and one altered strand. In the mutated region mismatching occurs. Mismatched DNA is cleaved chemically (piperidine potassium permanganate), eventually after labeling of mismatched bases by osmium tetroxide or hydroxylamine. Cleaved PCR products are shown afterwards by electrophoresis in the case of DNA alterations.

Although the described methods have been well established for analyzing genetic disorders or cancerous mutations, automatic sequencing (Section Sequencing) as alternative procedure is becoming more and more important and is considered to be the safest way to detect mutations [61].

11.3. PCR Analysis in Evolution and Taxonomy

Apart from characterizing DNA of individuals (see also Section Detection of Genetic Disorders or Cancerous Cells), PCR technology may also be applied for epidemiological purposes and phylogenetic or phylogeographic studies [62]. Generally, similarity or diversity of organisms is to be shown and measured.

However, precondition for analyzing genetic relationships is the occurrence of polymorphisms. Polymorphisms are characteristics (i.e., DNA sequences) that evolve continuously or exist in different forms. Examples for commonly known polymorphisms are blood group antigens, isoenzymes, human leukocyte antigen (HLA) antigens, satellite DNA [mini- and

microsatellites, variable number of tandem repeats (VNTRs)].

Depending on the period that is to be examined (few generations, centuries or thousands of years) different kinds of polymorphisms must be examined. For short periods or high resolving procedures characteristics that develop fast are studied, e.g., DNA sequence of introns, mitochondrial DNA [63], [64] or microsatellites. For examinations spanning large periods DNA sequences that evolve slowly are analyzed, for example, extremely conserved t- or rRNA genes. Particularly PCR-based analysis of rRNA genes or ribosomal spacer regions have become an important tool for taxonomic questions and differentiation of species or subspecies (see also Section Universal PCR) [53], [54], [65].

Commonly applied methods for studying relationship are blood group serology, analysis of amino acid sequences, restriction fragment length polymorphism (RFLP) [66], PCR typing of microsatellite or HLA genes, random amplified polymorphic DNA (RAPD), or DNA sequencing. RFLP, PCR typing, and RAPD will be discussed in the following sections and may be summarized as fingerprint methods, since they all lead to a “bar code”-like result, the genetic fingerprint [67]. Altogether, fingerprinting methods are an extremely useful tool for differentiation and characterization of organisms.

11.3.1. *Restriction Fragment Length Polymorphism*

For RFLP DNA (chromosomal, plasmid DNA, or PCR amplified DNA) is restricted with endonucleases, so that different DNA fragments are generated that can be separated electrophoretically. Fragment polymorphism is then visualized by staining DNA with ethidium bromide or by hybridization with labeled probes. Banding patterns are supposed to show characteristic differences [51], [68].

A very common application of RFLP fingerprints is analysis of eucaryotic DNA microsatellites. Satellite DNA is therefore amplified and marked as probe for hybridization with restricted and electrophoretically separated genomic DNA. Resulting hybridization patterns are characteristic for each individual.

11.3.2. *PCR for Typing Satellites or HLA Genes*

Satellites consist of repetitive DNA sequences (simple mononucleotide to pentanucleotide repeats) of variable number and have become the marker of choice in many research fields in biology, animal and plant breeding, such as genome mapping, population studies, testing of parentage and kindship, cancer diagnostics as well as forensic identification [69]. Microsatellites are abundant, codominant, highly polymorphic and spread across the whole genome.

One of the major fields of application is linkage analysis, where microsatellite markers, whose alleles are seen preferentially by those members of families with the trait of interest (e.g., milk yield, disease, disease resistance) are said to be linked and should therefore colocalize with the responsible gene.

On the other hand, the alleles of unlinked markers should be inherited equally between the different phenotypes. The likelihood that any preferential inheritance seen for a certain marker is the result of genuine linkage as opposed to simple chance is expressed as LOD scores. Requirements for linkage analysis increase with the number of loci being involved in the disorder or phenotypic trait.

Complex traits that are not inherited in a simple Mendelian fashion but by several to many loci with smaller effects on the trait exhibit a great challenge on family numbers and statistical analysis involved. Such traits are called “quantitative trait loci” (QTL). They can be studied by QTL analysis [70].

Usually many loci (microsatellites) are analyzed in parallel and thus multiplex PCR assays are a must for such type of analysis. Multiplex PCR products generated not only differ in length, but also in the fluorophores covalently attached to the 5'-end of forward or reverse primers. Thus even PCR products having the same length may be differentiated by their fluorophores. Amplification products are separated by high-resolution polyacrylamide gel electrophoresis, allowing one single nucleotide length difference to be analyzed. Laser-induced fluorescence signals of PCR products allows for online monitoring of electrophoresis patterns. Amplification generates characteristic sets of PCR products for individuals or groups (Fig. 15). Typing of HLA genes is described in Section Tissue Typing.

Figure 15. Typing of microsatellites from three generations of one family by fingerprint analysis and deviated family tree. Maternal grandmother (lane 1) and grandfather (lane 3) possess two different alleles (black and white; grey and yellow). Paternal grandmother (lane 11) and grandfather (lane 13) are homozygous (yellow). Consequently the father (lane 12) is also homozygous (yellow). The mother (lane 2) is heterozygous (black and grey). Progenies are heterozygous possessing all but one (black and yellow) identical alleles (grey and yellow).

11.3.3. *Random Amplified Polymorphic DNA*

RAPD PCR is based on unspecific binding of primers to unknown DNA sequences. Primers for this purpose are short and composed randomly. Unspecific amplicons generated initially during RAPD reactions are later on amplified specifically, so that a characteristic set of distinct PCR products is generated (Fig. 16). A typical temperature profile for RAPD consists of two initial cycles with extremely low annealing temperatures (40 °C) for several minutes followed by 20 – 30 regular PCR cycles. Furthermore, Mg^{2+} ion concentration may be elevated [71], [72]. RAPD techniques are widely used in plant breeding research and for characterization of bacterial isolates [73]. One of the major problems of this technique is low reproducibility [74] of results and low discriminatory power [75], [76]. RAPD techniques are also designated as arbitrarily primed PCR (AP-PCR).

PCR fingerprinting methods similar to RAPD are ERIC-PCR (enterobacterial repetitive intergenic consensus PCR) [77], DAF (DNA amplification fingerprinting) [78] and REP-PCR (repetitive extragenic palindromic PCR) [79], [80].

Figure 16. PCR fingerprinting analysis. Different species (lane 1 – 8) have been subjected to DAF PCR showing different patterns on an agarose gel. M1, M2 molecular weight marker.

11.3.4. *Analysis of Fingerprints*

Besides visual analysis, many computer-based image analyzing systems exist. Comparison of fingerprint patterns and quantifying of similarity as a measure for relatedness are based on mathematical methods ["Dice coefficient" [81], UPGMA (unweighted pair group method, averages)] [82]. Computer software packages like PHYLIP (Felsenstein) simplify analysis and help to construct figures of relationships (dendrograms). A precondition to evaluate time course in phylogeny is the knowledge of mutational rates of the examined loci.

11.3.5. *Restrictions and Future Aspects*

Since the beginning of the 1990s developments in automatic DNA sequencing reduced the importance of described fingerprinting methods. Comparison of genetics may also be performed on the basis of completely sequenced genes [83]. The only precondition for routine and comparative sequencing is that sufficiently conserved DNA regions exist for the construction of primers. Sequencing of PCR products for analyzing relationship altogether allows detection and characterization of smallest polymorphism, i.e., point mutations.

PCR based fingerprinting methods became after all an important tool for molecular archeology. To reduce DNA loss due to aging, particularly short DNA fragments are amplified that existed originally in several copies.

Two well known examples for PCR based phylogenetic studies are rRNA gene analysis for taxonomic purposes or high resolving mt (mitochondrial) DNA analysis for identification of singular (vertebrate) species.

11.4. Tissue Typing

Major histocompatibility complex (MHC) molecules, belonging to three different groups of cell surface antigens, are coded by extremely polymorphic genes (10 – 50 alleles per locus) in the HLA (human leukocyte antigen) region of human chromosome 6. Due to high genetic variability recombination results in enormous polymorphisms so that every individual may be identified by its individual MHC antigen combination.

MHC I molecules are expressed on the surface of virtually every cell type containing nuclei. They represent the classical transplantation antigens and may play a key role in the activation of killer cells. MHC II molecules are mainly expressed by cells belonging to the immune system. These cells internalize antigens and present them to others for activation of immunological reactions.

One of the major problems in transplantation medicine is identification of organs as "not-self" by the immune system followed by destruction. To avoid this reaction high similarity in MHC I antigens and HLA loci is needed. Typing of HLA loci is also applied for forensic purposes to identify offenders. Meanwhile convenient commercial kits for tissue typing have become available.

Furthermore, several diseases are described to be associated with certain HLA types, so that identification of HLA types may indicate an elevated risk to suffer from these diseases and accelerate diagnosis.

Besides serological methods for differentiation of MHC antigens, PCR with consecutive analysis of amplicons is becoming more important [84]. By this way antigen differences are not only detected but also characterized immediately.

After amplification of HLA genes, amplicons may be characterized by three different procedures:

1. Enzymatic restriction (Section Restriction Analysis),
2. Denaturing gradient gel electrophoresis (DGGE) (Section Denaturing Gradient Gel Electrophoresis (DGGE)), or
3. Hybridization with allele-specific oligonucleotides (ASO) (Section Allele-Specific Oligonucleotides (ASOs)) [42]

11.5. PCR in Food Analysis

During public discussions concerning production and trade of genetically modified food, the necessity of sensitive and specific detection methods for modified food became evident. With these methods detection of even small amounts of modified food in mixed products must be possible. Today, PCR is well established in food analysis as a most sensitive procedure for detection of genetically modified crops [85] or microbial contamination (Section Detection of Pathogenic Agents).

The detection of genetically modified organisms (GMOs) is only possible if the genetic modification, i.e., sequence is known. For the detection of GMOs in the food sector the types of sequences listed in Table 5 have been applied if intact recombinant DNA is available.

Table 5. Examples for sequences which may be used to detect genetically engineered food

Selective marker genes	
npt II:	neomycin-/kanamycin-/ G 418 resistence (*E. coli*)
hph; hpt:	hygromycin resistence (*E. coli*)
aac C1:	gentamycin resistence (*Micromonospora purpurea*)
cat:	chloramphenicol resistence (*E. coli*)
aad A:	spectinomycin resistence (*E. coli*)
dhfr-Mtx:	dihydroxyfolate (*E. coli,* mouse)
bla:	ampicillin resistence (*E. coli*)
Regulators	
35 S:	35 S promoter, terminator (*CaMV*)
nos:	nopalin synthase gene (promotor and terminator) (*Agrobacterium tumefaciens*)

Official methods now exist for the detection of DNA of glyphosate-tolerant soybeans (Roundup Ready, Monsanto, USA). Glyphosate is a herbicide inhibiting the most important enzyme in the metabolism of aromatic amino acids in plants: Enolpyruvylshikimi-3-phosphate synthase (EPSPS). Glyphosate tolerance of soybeans is caused by a genetic construct coding for EPSPS of *Agrobacterium sp*. and a transfer peptide from *Petunia Hybrida* (transit signal sequence) for introducing of EPSPS into chloroplasts. To detect this genetic modification primer B1 5′-TGA TGT GAT ATC TCC ACT GAC G-3′ and B2 5′-TGT ATC CCT TGA GCC ATG TTG T-3′, derived from the CaMV/35S promoter sequence and the transit signal sequence, respectively, are applied. The recommended annealing temperature for this PCR is 62 °C. PCR results are confirmed by hybridization with a fluorescein-labeled probe (5′-fluorescein-GGG TCT TGC GAA GGA TAG TG-3′).

A major drawback of conventional PCR is lack of accurate quantitative information about the relative GMO concentrations in food mixtures.

Therefore, real-time PCR assays are applied using multiplex PCR techniques [86]. Apart from detection of the genetically modified sequence an endogenous reference gene is detected, allowing for the relative quantification of the GMO content. In this way GMO contents of less than 0.01% could be detected. However, most laboratories now adjust their estimates by comparison to a standard curve, i.e., a series of measurements from a DNA series with known GMO content.

11.6. PCR to Engineer DNA

Techniques such as cloning of genes, modifying genes (mutagenesis), or screening for recombinant clones has been considerably simplified by applying PCR methods.

11.6.1. *Cloning of PCR Products*

Genes of known sequence are easily amplified by PCR out of crude material avoiding the tedious and time-consuming task of screening DNA libraries with gene-specific probes.

Primers used to amplify genes can be designed with additional sequences (e.g., restriction sites) to facilitate insertion of the amplified DNA into cloning vectors. By using two different restriction sites (one in each primer) amplicons can be digested with two different restriction enzymes and thus can be inserted in a directed way into cloning vectors. One should keep in mind that most restriction enzymes do not cut DNA if the recognition sequence constitutes a terminal DNA sequence. Therefore, at least a few more bases should be added 5′ to the actual recognition sequence.

Most DNA polymerases do not generate blunt-ended amplicons but add a 3′-A. These amplicons can be directly inserted into special, T-A vectors engineered for this purpose containing a 5′ protruding T.

Direct cloning of PCR products into blunt-ended cloning vectors is also possible when using DNA polymerases (*Pfu*, Vent) producing blunt-ended amplicons.

Clones obtained by each of these methods may be screened for recombinant DNA using vector specific or insert specific primers.

11.6.2. *PCR Mutagenesis*

PCR is easily applied to generate mutated DNA, i.e., to insert, delete, or substitute DNA sequences or single bases. Mutagenesis is used for example to analyze the effect of mutated regions or even single bases in a gene on the corresponding protein or to investigate structure/function relationships of proteins.

Several methods are available to introduce mutations into a gene [87]. The most widely used PCR technique is overlap extension PCR. It is used to introduce point mutations (Fig. 17), deletions (Fig. 18) or insertions (Fig. 19) into a gene. Four primers (A, B, C, D) are necessary for this approach. Primer sequences C and D are complementary to the same DNA segment but to the opposite strands. Both primers contain a single base mismatched to the target sequence leading to the same sequence alteration (point mutation) in the two primary PCR products. PCR 1 (primers A and C) and PCR 2 (primers B and C) are performed in separate tubes. After amplification excess primers are removed, PCR products from the two PCRs are mixed, denatured and allowed to reanneal. Products which recombine by overlapping of complementary segments are elongated to maintain dsDNA and subsequently these products are amplified with primers A and B. Products from this PCR contain the site-specific mutation. Deletion of DNA segments by overlap extension PCR are

performed with primers C and D complementary to different segments of the target DNA and containing sequences at their 5′ end which are complementary to each other. The deleted DNA segment is flanked by the 5′ end of each primer C and D that matches the target sequences. Two different PCRs are performed in separate tubes, excess primers are removed from the PCR products, mixed and subjected to a PCR with primers A and B. Insertion of small DNA segments by overlap extension PCR are carried out with primers C and D derived from the same target sequence but complementary to opposite strands. At their 5′ end sequences are added which are complementary to each other. The length of these sequences is limited by the oligonucleotide synthesis procedure. After PCR with primers A/C and B/D, performed in separate tubes, both reactions are mixed, excess primers are removed and a PCR with primers A and B is performed. Overlap extension PCR is also used to combine gene fragments from unrelated sequences. In this case primers C and D are derived from different target DNAs and contain additional sequences at the 5′ ends which are complementary to each other. Further manipulations are the same as for introducing insertions (Fig. 19).

Figure 17. Site-specific mutagenesis by overlap extension PCR. Four primers (A, B, C, D) are necessary for this approach. Primer sequences C and D are complementary to the same DNA segment but to the opposite strands. Both primers contain a single base mismatched to the target sequence leading to the same sequence alteration (point mutation) in the two primary PCR products. PCR 1 and PCR 2 are performed in separate tubes. After amplification excess primers are removed, PCR products from the two PCRs are mixed, denatured and allowed to reanneal. Products which recombine by overlapping of complementary segments are elongated to maintain dsDNA and subsequently these products are amplified with primers A and B. Products from this PCR contain the site-specific mutation.

Figure 18. Deletion of DNA segments by overlap extension PCR. Primers C and D are complementary to different segments of the target DNA and contain sequences at their 5′ end which are complementary to each other. The deleted DNA segment is flanked by the 5′ end of each primer C and D that matches to the target sequences. Two different PCRs are performed in separate tubes, excess primers are removed from the PCR products, mixed and subjected to a PCR with primers A and B.

Figure 19. Insertion of small DNA segments by overlap extension PCR. Primers C and D are derived from the same target sequence but complementary to opposite strands. At their 5′ end sequences are added which are complementary to each other. The length of these sequences is limited by the oligonucleotide synthesis procedure. After PCR with primers A/C and B/D, performed in separate tubes, both reactions are mixed, excess primers are removed and a PCR with primers A and B is performed.

11.7. PCR for Analysis of Gene Expression

The detection of gene expression, i.e., synthesis of mRNA may be accomplished in several ways. Widespread methods for studying specific RNA molecules are in situ hybridization, Northern blots (⟶ Genetic Engineering – Nucleic Acid Hybridization), or RT-PCR.

In many cases the detection of a specific RNA molecule can be used to diagnose the existence of an infectious (Section Amplification) or genetic/cancerous disease. In both areas it is of importance to monitor the presence and the amount of viral RNA or cancerous mRNA indicating active infection or tumor development [35], [88]. With increasing knowledge of expressed gene sequences the expression patterns will reflect the biological status of cells with high precision yielding refinements in diagnostic strategies [89]. These applications underline the importance of quantitative (RT)-PCR technologies (Chap. Quantitative PCR).

1. Introduction

Reactive distillation (RD) is a process in which a catalytic chemical reaction and distillation (fractionation of reactants) occur simultaneously in a single apparatus. From the reaction engineering view point, it can be classified as a two-phase countercurrent fixed-bed catalytic reactor.

This integrated reaction – separation technique is also known as catalytic distillation (CD) or reaction with distillation (RWD). According to [1], CD is a process in which a heterogeneous catalyst is localized in a distinct zone of a distillation column. RD is a more general term for this operation, which does not distinguish between homogeneously and heterogeneously catalyzed reactions in distillation columns. RWD is a trademark of the Koch Engineering Company for reactive distillation technology that uses their KataMax packing structures. This article exclusively deals with RD processes that operated with a heterogeneous catalyst system, i.e., CD technology.

The most important advantage of CD technology for equilibrium-controlled reactions is the elimination of equilibrium limitation of conversion by continuous removal of reactants or products from the reaction mixture. For example, unconverted reactants are removed in the vapor stream, while low-boiling products are fed downstream in the liquid phase, but the opposite case is also possible. It is the application of Le Chatelier′s principle to displace the chemical equilibrium by increasing the concentrations on the one side of the reaction and decreasing it on the other. The chemical composition at this equilibrium point can be calculated by means of the Gibbs energy of reaction at a given temperature. Activities must be used to recalculate the composition from the equilibrium constant, (i.e., the molar fractions of the components).

Usually, a partially converted reaction mixture, nearly in chemical equilibrium, leaves the fixed-bed reactor section and enters the CD column in the fractionating zone to ensure the separation of products from feedstock components. The fractionated unconverted feed components enter the catalytic section for additional conversion. The catalyst packing zone is installed in the upper or lower-middle portion of the column, with normal distillation sections above and below.

CD technology has several advantages over conventional operating methods, such as a fixed-bed reactor connected to a fractionating column, in which the distillate or bottoms are recycled after further separation steps. Apart from increased conversion, the following benefits can be obtained [1]:

- The most important benefit of CD technology is the lower capital investment, because two process steps can be carried out in the same device (process intensification). Such integration leads to lower costs for pumps, piping, and instrumentation.
- If CD is applied to an exothermic reaction, the reaction heat can be used to vaporize part of the surrounding liquid, which represents three fundamental advantages: The maximum temperature in the structured catalytic packing is limited to the boiling point of the reaction mixture, so that the danger of *hot spots* is reduced significantly. Also, extremely simple and reliable temperature control is achieved. In addition, the integration of reaction heat in the distillation process leads to energy savings by reducing reboiler duty.
- Product selectivities can be improved owing to fast removal of reactants or products from the reaction zone. Thus, the probability of consecutive reactions, which may occur in conventional operation, is lowered.
- If the reaction zone in the CD column is located above the feed point, poisoning of the catalyst can be avoided. This leads to longer catalyst lifetime compared to conventional plant.

There are three important constraints for applying CD technology to catalytic chemical reactions:

– The use of CD technology is only possible if the temperature window of the vapor – liquid equilibrium is equivalent to the reaction temperature. By changing the column operating pressure, this temperature window can be altered. The flexibility in temperature is not only restricted by the fact that two phases are required for disillation. Also the thermal stability of the catalyst can limit the upper operating temperature of the distillation column.
– Because of the necessity of wet catalyst pellets, the chemical reaction must take place entirely in the liquid phase.
– As it is very expensive to change the catalyst in the structured packing of a CD column, only catalysts with a long lifetime are suitable.

In the literature, it is also reported that endothermic reactions are not suitable for the CD technology, because it condenses vapor. Although endothermic reactions require more reboiler duty and therefore exhibit no large energy savings, there are no restrictions with regard to the application of the technology [2].

Chemical reactions which benefit from CD technology must fulfill the above-mentioned criteria. They include etherifications, esterifications, transesterifications, hydrations, hydrolysis, condensations, hydroisomerizations, oligomerizations, alkylations, and transalkylations.

2. Mathematical Modeling of Reactive Distillation Processes

2.1. Equilibrium-Based Models

Multicomponent separation processes, such as normal distillation processes, have been modeled by using the equilibrium-stage concept for a century. Therefore, early works on reactive distillation also used the *equilibrium-stage model* to simulate reactions with superimposed distillation.

The principal assumption of the equilibrium-stage model is that the vapor and the liquid stream that leave the stage are in thermodynamic equilibrium. In real distillation columns, of course, the residence time is too short to reach total equilibrium. For this reason, other efficiencies have been introduced into the model (e.g., Murphree efficiency, vaporization efficiency, etc.). MESH equations, which consists of:

– Material balance
– Equilibrium relations
– Summation equations
– Heat equations

are used to simulate conventional distillation columns. To introduce the chemical reaction further equations are needed to simulate reactive distillation processes (→ Reaction Columns, Chap. 2.). The simplest way to consider chemical reactions is to use an equilibrium constant, but many reactions are not fast enough to reach chemical equilibrium in one theoretical stage. Therefore, it is often necessary to use kinetic expressions, with depend on temperature and the concentration of each component.

2.2. Rate-Based Models

To describe the real phenomena of mass transfer in distillation processes in more detail, a second-generation nonequilibrium model was developed by Krishnamurthy and Taylor [3]. A nonequilibrium stage (Fig. 1) represents either a single tray or a section of packing in a column.

Figure 1. Nonequilibrium based stage model without feed and side streams

Contrary to the equilibrium-based stage model, this rate-based model treats the vapor and

liquid phases separately and combines them by means of a mass transfer rate and a heat transfer rate through the interfacial area. The total mass transfer rates are:

$$N_j^{\mathrm{V}} = c_{\mathrm{tj}}^{\mathrm{V}} k_j{}^{\mathrm{V}} a_j (y_j - y_j{}^{\mathrm{l}}) + N_{\mathrm{tj}}^{\mathrm{V}} y_j \quad (1)$$

$$N_j{}^{\mathrm{L}} = c_{\mathrm{tj}}^{\mathrm{L}} k_j{}^{\mathrm{L}} a_j (x_j{}^{\mathrm{l}} - x_j) + N_{\mathrm{tj}}^{\mathrm{L}} x_j \quad (2)$$

where $N_j{}^{\mathrm{V}}$ or $N_j{}^{\mathrm{L}}$ are the vectors of molar fluxes of the vapor or liquid stream, respectively, c_{tj} are the molar densities, k_j are the matrices of mass transfer coefficients, a_j is the specific interfacial area, and $N_{\mathrm{t}j}{}^{\mathrm{V}}$ or $N_{\mathrm{t}j}{}^{\mathrm{L}}$ are the total mass transfer rate of the vapor or liquid stream, respectively [4].

At the interface of each stage j phase equilibrium (E equation, see above):

$$K_{ij} x_{ij}{}^{\mathrm{l}} - y_{ij}{}^{\mathrm{l}} = 0 \quad (3)$$

and summation equations (S equations, see above) for each component i:

$$\sum_i y_{ij}^I - 1 = 0, \quad (4)$$

and

$$\sum_i x_{ij}^I - 1 = 0 \quad (5)$$

must be fulfilled.

To simulate the reactive distillation process, an expression for the reaction rate $r_{ij} = f$ (temperature, concentrations/activities) must be added. For catalytic distillation the chemical reaction is taken into account in the material balance of the bulk liquid phase

$$(1 + s_j{}^{\mathrm{L}}) L_j x_{i,j} x_{i,j-1} - L_{j-1} - f_{ij}{}^{\mathrm{L}} - N_{ij}{}^{\mathrm{L}} - r_{ij} = 0 \quad (6)$$

where $s_j{}^{\mathrm{L}}$ is the liquid side-withdrawal and $f_{ij}{}^{\mathrm{L}}$ is the feed flow rate of component i to stage j in the liquid phase. For many catalytic distillation processes, liquid – catalyst mass transfer must also be considered.

The reaction heat ΔH_{r} which is produced (exothermic reaction) or consumed (endothermic reaction) is considered in the heat balance of the liquid phase (see Figure 1).

Yuxiang and Xien [5] used this nonequilibrium stage model with simplified expression of the reaction kinetics based on concentrations to simulate the synthesis of MTBE, which they investigated experimentally in a column filled with catalyst granules in cloth pockets. The results of their simulation agreed fairly well with the experiments. However, Sundmacher and Hoffmann [6] investigated MTBE formation over a broad concentration range and found that the macrokinetics could be correctly described only by using liquid-phase activities for the intrinsic reaction kinetics and liquid – solid mass transfer.

The equilibrium-based stage model is an excellent *pragmatic approach* to simulate reactive distillation processes, especially those with homogeneous reactions. This model is part of all available process simulators (e.g., RADFRAC in ASPEN-PLUS, Aspen Technology, Inc.). For a *detailed study* of the superimposed distillation and interactions between reaction and mass transfer a rate-based approach is preferred (e.g., RATEFRAC in ASPEN-PLUS, Aspen Technology, Inc.).

3. Design of Reactive Distillation Processes

3.1. Procedures for Process Design Studies

Only a few systematic methods are available for the process design of multifunctional units such as reactive distillation columns. One method is the concept of reactive distillation lines with reactive azeotropes by Buzad and Doherty [7], Bessling et al. [8] and Stichlmaier et al. [9]. A brief description of this method is given below.

Figure 2 shows the transformation of coordinates for the equilibrium reaction $\mathrm{A} + \mathrm{B} \rightleftharpoons \mathrm{C}$. This transformation reduces the equilibrium concentration of component C to a single point on the line of the transformed coordinates A and B. Mathematically one can define a chemical equilibrium reaction by Equation 7:

$$\nu_{\mathrm{a}} \mathrm{A} + \nu_{\mathrm{b}} \mathrm{B} \ldots \rightleftharpoons \nu_{\mathrm{p}} \mathrm{P} + \ldots, \quad (7)$$

where ν_i are the stoichiometric coefficients and P the desired products. The transformed liquid and vapor coordinates for an arbitrary component i, i.e., X_i and Y_i, are given by Equation 8, [10].

$$X_i = \frac{x_i - \frac{\nu_i x_\mathrm{R}}{\nu_\mathrm{R}}}{1 - \frac{\nu_\mathrm{T} x_\mathrm{R}}{\nu_\mathrm{R}}} \tag{8}$$

$$Y_i = \frac{y_i - \frac{\nu_i y_\mathrm{R}}{\nu_\mathrm{R}}}{1 - \frac{\nu_\mathrm{T} y_\mathrm{R}}{\nu_\mathrm{R}}}, \tag{9}$$

where R is a chosen reference component. R can be reactant or a product component. The stoichiometric coefficient ν_T in these equations is defined as:

$$\nu_\mathrm{T} = \sum_{i=1}^{\mathrm{NC}} \nu_i \tag{10}$$

Figure 2. Transformation of coordinates for a equilibrium reaction A + B ⇌ C.

Both the vapor and liquid molar fractions of component P are set to zero, i.e., $X_\mathrm{P} = Y_\mathrm{P} = 0$. According to Equation (8), the transformed composition coordinates fulfill the unity constraints:

$$\sum_{i=1}^{\mathrm{NC}} X_i = \sum_{i=1}^{\mathrm{NC}} Y_i = 1 \tag{11}$$

By using these transformed coordinates for the feed components A and B, the mass balance and operating lines of a distillation column can be set up in the same way as for a system without a reaction. It reveals that feasible top and bottom compositions have to meet the lever rule (→ Distillation and Rectification, Chap. 4.2.2.) through the feed concentration and an appropriate distillation line, as shown in Figure 3. This is the same procedure as for conventional nonreactive systems.

Figure 3. Application of the concept of reactive distillation lines. As mass balance must be fulfilled, the feed concentration X_F is located on a straight line between the transformed concentrations X_D and X_B.

Figure 4 shows reactive distillation lines for the equilibrium reaction A + B ⇌ C in the presence of an inert component D. Note that product C is no longer necessary, because of the transformed-concentration coordinates between A and B (see Eq. 8). For a given feed concentration F, two process layouts can be derived. In design type I, component C decomposes, and B can be separated from A and D. With design type II, component C is formed, and the inert component D is separated from a mixture of A and B, which is in chemical equilibrium with C. If the equilibrium constant of the reaction A + B ⇌ C is increased, a reactive azeotrope appears along line AB (Fig. 5). According to Ung and Doherty [11] this reactive azeotrope is characterized by identical vapor and liquid transformed-concentration coordinates (Eq. 12).

$$X_i = Y_i \tag{12}$$

In this case the reactive azeotrope and the inert component D are nodes; components A and B are saddles. Therefore, in contrast to Figure 4, it is not possible to realize design type I (decomposition of C). Only design type II, i.e., the formation of C and separation of D at the top and A, B, and C at the bottom of the RD column, is feasible. The concept of reactive distillation lines with reactive azeotropes can also be extended to several other reaction types and to nonideal reactive distillation systems as well.

In collaboration between the chemical industry and European universities, two tools

Figure 4. Reactive distillation lines for an equilibrium $A + B \rightleftharpoons C$ in the presence of an inert component D (LB = low-boiling, MB = medium-boiling, HB = high-boiling).

Figure 5. Reactive distillation lines for an equilibrium reaction $A + B \rightleftharpoons C$ in the presence of an inert component D with a reactive azeotropic point (LB = low-boiling, MB = medium-boiling, HB = high-boiling).

have been developed for the design of RD processes, namely SYNTHESIZER and DESIGNER. SYNTHESIZER is based on the above-mentioned analogy between normal distillation processes and RD processes. It investigates the feasibility of RD for an existing process during re-engineering or in the planning stage for a new process. DESIGNER gives a more precise insight into the RD process with respect to column parameters (e.g., column diameter, etc.). It contains calculation procedures with equilibrium-based stage models as well as rate-based models for a specific process design [12].

Figure 6. Flowsheet for the process development of a CD technology (CSTR = continous stirred tank reactor) (∗: see Chapter 1)

3.2. Flowsheet for Process Development

Figure 6 shows a flowsheet as a conceptual basis for the development of a CD process.

The key feature of this flowsheet is the feasibility study followed by pilot plant experiments (optional) and a basic engineering concept. After using the above-mentioned tools for process synthesis and design (see Section 3.1), the parameters of a kinetic model must be determined in an appropiate experimental setup.

Simulation studies with a simple equilibrium-based stage model like, such as RADFRAC (ASPEN-PLUS), should reveal the optimal feed point to the CD column, the operating conditions of the CD column, and the position of the reaction zone in the CD column. As a first approximation, these studies can be carried out by

using equilibrium constants to incorporate the chemical reaction in the column. For a detailed investigation, it is recommended to use an appropriate reaction expression with the determined kinetic parameters in a conventional simulator.

In pilot plant experiments, which are carried out in a CD column with an inner diameter of 50 – 100 mm, the simulation studies are examined. As the process is iterative, these experiments are needed to check and to improve the simulations.

As the last step of the feasibilty study, all obtained results are fed into a final simulation to decide whether an RD or conventional setup (e.g., reaction section followed by separation steps with internal recycle streams) should be applied. Preferably, a rate-based model such as for example RATEFRAC (ASPEN-PLUS), is used to check whether any mass-transfer limitations interfere with the removal of reactants. Such limitations can cause undesired consecutive reactions in the reaction zone.

4. Industrial Applications

4.1. Commercial Packing Structures

All commercial CD packing structures have in common that the catalyst is located in a distinct zone of a distillation column. Apart from the problem of positioning these packing structures, adequate contact between catalyst surface and liquid phase must be ensured.

Nowadays, in most industrial processes macroporous acidic ion-exchange resins are used, but any other solid catalyst pellet can be placed in the pockets of a structured packing. As the entire catalyst structure must be removed from the distillation column to exchange the catalyst, one evident prerequisite for the catalyst is a long lifetime (more than about three years). Catalyst replacement means shutting down whole plants which results in a significant loss of costs and operating time.

CD Tech Catalyst Bales. This type of spatial configuration in a distillation column was first developed and commercialized by CR & L (Chemical Research & Licensing Company) in 1980 [13]. It is now licensed by CD Tech (Chemical Distillation Technologies), a joint venture between CR & L and ABB Lummus Crest. In this technology the catalyst is supported in a fiberglass cloth, which is wrapped with stainless steel wire mesh. The demister wire mesh has two tasks. First, it stabilizes the fiberglass packing; second, it provides the void space necessary for distillation. These fiberglass cloths are rolled into catalyst bales and stacked on sieve trays in the column (Fig. 7).

Figure 7. CD Tech catalyst bales

KataMax and KataPak Technology. Analogous catalytic packing configurations were developed in 1991/1992 independently by Koch Engineering Company as KataMax technology [14] and by Gebrüder Sulzer [15] as KataPak technology. Here the catalytic section in the CD column has a conventional corrugated structure, wire-cloth distillation packing which contains appropiate catalyst pellets for the desired reaction. The solid catalyst is held in an envelope of meshed and crimped screen, sealed at the edges. These envelopes are stacked together in modular blocks, so that the crimp of one envelope has a 90 degree angle of inclination to the crimp of the next. In this architecture, channels are formed for the rising vapor flow and descending liquid flow. At the intersections, they provide intensive mixing of vapor and liquid phases and radial distribution in a block. It is reported [16] that the performance

parameters of the KataMax packing (i.e., the hydraulic and mass transfer efficiencies) are similar to those of standard distillation devices (e.g., the Flexipac packing). At liquid loadings of $10-50\,m^3m^{-2}h^{-1}$ catalyst contact efficiency exceeded 75 – 90 %. Catalyst contact efficiency is the ratio of the rate constant of the catalyst in the packing to the rate constant of the catalyst in a stirred tank reactor for a simple liquid-phase first-order reaction at the same temperature.

Usually the catalyst content of KataMax or KataPak lies between 20 and 25 vol. %. For KataMax a HETP value (height equivalent to a theoretical plate) between 0.4 and 0.6 m can be used for simulation. For KataPak the HETP is 1.0 m at normal F factors (→ Distillation and Rectification, Chap. 8.2.1.). The specific surface area of KataMax is $210\,m^2/m^3$ and of KataPak, 85 or $125\,m^2/m^3$ (KataPak-S 170.Y or KataPak-S 250.Y, respectively).

The benefits of this type of packing are a very good distribution of liquid and vapor phases at a low pressure drop, efficient contact of the reactants with catalyst pellets and instantaneous distillative removal of reactants. Therefore, it combines excellent separation performance with an efficient mass and heat transfer for chemical reaction.

MultiPak Technology. This new structured catalyst packing was developed by Montz in 1998 in cooperation with the University of Dortmund [17]. In MultiPak technology the stacks are built up of alternating layers of meshed, but not crimped, catalyst envelopes and crimped structured distillation sheets. From the viewpoint of reaction and fractionating behavior, it has the same performance as KataMax or KataPak. The advantage of MultiPak is the identical geometric structure in an 80-mm laboratory packing and a 300- or 1000-mm pilot plant packing. Therefore, scaleup from pilot plant experiments to industrial plants is much easier. It is claimed that a defined flow pattern of vapor and liquid is achieved by this construction. This has advantages when resins are used as catalyst. As there is only liquid phase in the catalyst envelopes, the pellets are competely wetted under process conditions, and there is no swelling or shrinkage due to alternating contact with vapor and liquid. The disadvantage is a higher pressure drop along the structured packing.

Reactive Rings. The reactive rings of VEBA Oel [18] are based on packing bodies such as Raschig rings or Berl saddles. On the outer and inner surface of these bodies, macroporous ion exchange resins are bonded chemically or physically. For example, the active Raschig rings are prepared by using an open-celled sintered glass, which is impregnated with a mixture of styrene, a long chain alkane, *p*-divinylbenzene, and a radical starter (AIBN: azo*bis*isobutyronitril). After the polymerization procedure, it is sulfonated with chlorosulfonic acid to build up the catalytic performance.

This type of reactive rings have been used in an etherification process in a pilot plant column [6], [19].

Other Technologies. Another interesting, but as yet not commercialized, technology for immobilizing catalyst pellets in a distinct zone of a CD column is to incorporate a fixed-bed in the downcomer of a conventional tray column [20].

4.2. Industrial Catalytic Distillation Processes

Catalytic distillation can be used in catalytic chemical reactions which are limited by a chemical equilibrium. There are various reactions that satisfy this criterion, but only for etherification, esterification, and alkylation (synthesis of ethylbenzene or cumene) is this technology applied on an industrial scale. An overview of further possible applications can be found in [1], [19].

Etherification Processes (see also → Methyl *tert*-Butyl Ether). The application of CD technology to etherification is limited to synthesis of methyl *tert*-butyl ether (MTBE), ethyl *tert*-butyl ether (ETBE), *tert*-amyl methyl ether (TAME), and *tert*-amyl ethyl ether (TAEE).

Because of their good octane enhancing properties and low volatilities these ethers are excellent gasoline blending compounds (so-called oxygenates). Reduction of the tetraethyllead content in gasoline in the mid-1970s led to a dramatic increase in the demand for octane enhancers, with MTBE being used increasingly.

Driven by the U.S. Reformulated Gasoline Program, which mandated a minimum oxygen content in gasoline of 2 %, world MTBE production has now reached ca. 19×10^6 t/a [21]. The successful use of CD technology in MTBE production led to its worldwide establishment.

Table 1 summarizes processes for ether production based on CD technology. As shown in the simplified process flow diagram for the ETHERMAX process (Fig. 8), all processes have in common a reactor section followed by a CD column. There is no industrial process in which the whole conversion is performed in a single CD column. A partially converted mixture from the reactor section, which is nearly in chemical equilibrium, enters the CD column below the catalyst packing zone to ensure the separation of the ether from the feed stream. The catalyst packing is installed in the upper middle of the column, with normal distillation sections above and below.

Usually, the reaction of the isoalkene with methanol or ethanol is conducted in the presence of a slight stoichiometric excess of the alcohol. In addition to the advantages of a higher selectivity for the ether (lower formation of C_8 and C_{10} dimers) and shifting of the chemical equilibrium to the product side, this leads to a secure process control. In the absence of the alcohol in the reaction zone of the CD column exothermic dimerization and oligomerization of the C_4 and C_5 alkenes takes place at high reaction rates. A sharp and excessive temperature rise (hot spot) causes irreversible catalyst deactivation and catalyst damage. The excess alcohol is collected in the overhead of the CD column and separated from the hydrocarbon stream by extraction with water.

In the case of MTBE production, conversions of up to 99.9 % are possible by using this technology, if sufficient ether is present at the bottom of the column. Because of a minimum boiling azeotrope in the binary MTBE – methanol system, the ether carries the alcohol into the reaction zone of the CD column. This unusual vapor – liquid behavior and the high difference in the heat of vaporization between C_4 hydrocarbons and methanol are possibly responsible for the known multiple steady states in CD column operation [19], [22].

The TAME process usually gives lower conversions of 91 – 95 %.

Esterification Processes. Esterification is a good example for the beneficial use of the CD technology. In conventional operation the recovery of methyl acetate from the reactor outlet stream is complicated, because methanol forms a low boiling azeotrope with water and the separation of water from unconverted acetic acid is difficult. Due to these separation problems, the old Eastman Kodak process used a reactor coupled with eight distillation columns and an extraction column [24].

In the reactive distillation process, almost pure methyl acetate can be collected in the overhead of a single CD column at acetic acid conversions of greater than 99 %. The Eastman Kodak process uses sulfuric acid as catalyst [25] but a heterogeneous catalyst system (acid ion-exchange resin) can also be used successfully [26].

The conceptual basis for the successful implementation of reactive distillation in methyl acetate synthesis is shown in Figure 9. There are four zones in the column, which ensure the fairly high conversion. Acetic acid is separated from methyl acetate at the top of the column (zone I). In zone II, an extractive distillation section below the acetic acid feed extracts water from methyl acetate. The reaction takes place in the middle of the column (zone III). At the bottom (zone IV) methanol is fed and stripped from descending byproduct water.

Alkylation Processes. CD-technology is also applied for alkylation reactions in the case of ethylbenzene and cumene manufacture [1]. As the two processes are fairly similar, only the cumene process is discussed here.

In the CDCUMENE process, CD Tech catalyst bales are filled with an acidic, wide-pore zeolite catalyst, for example, zeolite Y, β or ω [27]. The bales are stacked in the middle of a distillation column. Below the reaction zone propene is fed; benzene is passed as reflux to the top of the column. The propene concentration in the reaction zone is held fairly low to slow down a side reaction in which diisopropylbenzene (DIPB) and triisopropylbenzene (TIPB) are formed. The cumene product with impurities of ethylbenzene and *n*-propylbenzene, is taken from the bottom of the column. The overhead pressure of the CD column is maintained at 5 bar.

Table 1. Overview of CD processes for ether production [23]

Process (licensor)	Process description	Catalyst	Market share∗
ETHERMAX (UOP)	fixed-bed tubular reactor or adiabatic recycle reactor followed by a reactive distillation column with *KataMax Packing*	sulfonated ion-exchange resin	ca. 32 %
CDMTBE & CDTAME (CD-Tech)	adiabatic reactor operating at the boiling point followed by a reactive distillation column with *CD Tech Bales*	acidic ion-exchange resin	ca. 58 %
CDETHEROL (CD-Tech)	adiabatic fixed-bed reactor operating at the boiling point followed by a reactive distillation column with *CD Tech Bales*	trifunctional ion-exchange resin	–
CATACOL (IFP)	recycle reactor, fixed-bed reactor followed by a reactive distillation column	acidic ion-exchange resin	ca. 10 %

∗ For MTBE, produced by CD technology in 1997

Figure 8. Simplified flow diagram for the ETHERMAX process

Figure 9. Methyl acetate synthesis with CD technology

The advantages of CD technology in cumene synthesis are lower formation of oligo-isopropylbenzenes (DIPB and TIPB), higher catalyst lifetime, and a higher conversion of benzene [28]. The internal benzene recycle to the reaction zone, which is a result of the distillative cumene – benzene separation in the lower portion of the column, ensures the observed higher conversion.

1. Introduction

Water is an integral part of several “high-tech” manufacturing and processing industries. With severe processing requirements come stringent demands on all the raw materials and manufacturing components, included process water. Ultrapure water (UPW) is essentially a “high-tech” material as well. Consequently, significant technological efforts and expense are devoted to purifying water to severe standards.

Ultrapure water is produced in a series of separation units, the final step processing being primarily mixed-bed ion exchange (MBIE). MBIE is preceded by a range of stages where salts, biological contaminants, organic chemicals (usually collectively referred to as total organic carbon, or TOC), and dissolved gases are removed. These technologies include membrane processes (ultrafiltration, reverse osmosis RO, and pervaporation), adsorption typically on activated carbon for TOC and chlorine removal), disinfection e.g., by UV-light, degasification, or — most usually — a combination of these.

Industries that require ultrapure water include:

1. Power generation — Steam cycle water chemistry is critical to sustained operation of nuclear and coal-fired power plants. Ultrapure water processing occurs in three major areas of the plant production of make-up water, condensate polishing, and reactor water clean-up. Each of these applications has specific requirements for water quality and uses a range of different processes to achieve these requirements, including deep-bed ion exchange, powdered resin ion exchange, degasification and reverse osmosis.
2. Specialty materials processing — As the technology in the area of advanced materials becomes more and more complex, the purity of chemicals involved with their production and processing must also increase. Requirements for ultrapure water in the microchip and microelectronics industry are even more severe than for electrical power companies since contaminants, both ionic and particulate materials can effectively destroy microchip surfaces.
3. Biomedical and life science applications — The primary pharmaceutical applications for ultrapure water processing are: water for injection (WFI) and manufacturing of medicines. The separation requirements for pharmaceuticals are aimed at eliminating pyrogens (low molecular mass organic molecules — typical of membrane decay due to microbial decay that can cause fever. In addition, ultrapure water is used extensively as a diluent for dialysis. Another life science application of ion exchange includes water reuse on space missions.
4. Boiler feed water purification — ultrapure water is also required as boiler feed water in chemical plants, such as ethylene and ammonia production. High purity water is also needed by the pulp and paper plants.

[Top of Page]

2. Definition

Standards for ultrapure water vary among industries, but UPW is typically defined as having electrolytic conductivity less than 0.1 µS/cm. For comparison, the theoretical conductivity of pure water is 0.054 µS/cm at 25 °C. To be classified as ultrapure water, the ionic concentration must be less than 20 µg/L (industry often uses parts per billion, ppb NaCl or $CaCO_3$ equivalent). The NaCl/$CaCO_3$ equivalent of a specific ion is calculated by multiplying the actual concentration by the ratio of the ion equivalent weight and NaCl or $CaCO_3$ equivalent weights (58.5 and 50)

$$\mathrm{ppb}_{\mathrm{NaCl}} = \mathrm{ppb}_i \frac{\mathrm{EW}_{\mathrm{NaCl}}}{\mathrm{EW}_i}$$

$$\mathrm{ppb}_{\mathrm{CaCO_3}} = \mathrm{ppb}_i \frac{\mathrm{EW}_{\mathrm{CaCO_3}}}{\mathrm{EW}_i}$$

where EW is the equivalent weight and the index i denotes “ion”.

In microelectronics rinsing water — in particular, microchip manufacturing — sub parts per trillion (ppt, ng/L) concentrations of contaminants are achieved. For many semiconductor manufacturers, the desired contaminant concentrations are at, or below, the detection limits for most analytical equipment. On-line data are often confirmed with manually collected samples (grab samples) and external laboratory analysis. The operating temperature of the water is process dependent, although some processes require hot UPW (typically below boiling temperature), common applications require water between 22 – 28 °C. The allowable level of dissolved oxygen also depends on the process; some processes have no concentration limits, while others require no or small amounts of dissolved oxygen.

2.1. Ionic Purity — Conductivity and Resistivity

Ionic concentration limits in ultrapure water may be expressed for specific ions — where the concentration is monitored by on-line ion chromatography — or by the total conductivity of solution. In dealing with ultrapure water, resistivity, i.e., reciprocal conductivity, is easier to follow. Tables 1 and 2 list the water quality standards for ionic species in semiconductor grade water (Balazs Laboratories). Specifications change with system requirements and analytical capabilities, but the U.S.P., the ASTM, the Electrical Power Research Institute (EPRI), and other organizations post updates frequently. Some of this information is available on the World Wide Web (e.g., http://www.balazs.com and http://www.millipore.com).

Table 1. Semiconductor specifications for metals content (ppb (µg/L)) of ultrapure water by determined inductively coupled plasma-mass Spectrometry (ICP/MS) (Courtesy of Balazs Laboratories, 1993)

Metal	Attainable concentration	Acceptable concentration	Alert concentration	Critical concentration
Aluminum	0.007	0.05	> 0.0	0.20
Barium	0.002	0.01	> 0.05	0.10
Boron	0.3	< 2.0		
Chromium	0.008	0.03	> 0.03	0.05

Ca^{2+}	< 0.02	< 0.1	> 0.01	> 0.2
Mg^{2+}	< 0.02	< 0.1	> 0.01	> 0.2
Anions				
F^-	< 0.1	< 0.1	> 0.02	–
Cl^-	< 0.02	0.1	> 0.02	> 0.5
Br^-	< 0.02	< 0.1	> 0.01	> 0.5
NO_3^-	< 0.02	< 0.1	> 0.01	> 0.5
HPO_4^{2-}	< 0.02	< 0.1	> 0.01	> 0.5
SO_4^{2-}	< 0.05	0.1	> 0.02	> 0.5

Power plant water chemistry has somewhat different UWP standards depending on the type of power plant, the water used to cool the condensers and the location within the plant. The primary objective of condensate polishing is to minimize erosion and corrosion. Elevated contaminant concentrations result in problems, due to chemical reactions, particularly in crevices, where water droplets concentrate these chemicals and allow rapid interaction with material surfaces. Routine sources of these contaminants are the materials of construction themselves and chemicals added to regulate water chemistry. Major problems may occur with leaks in condenser tube that add large amounts of contaminants rapidly to the system. Under these conditions, condensate polishers have the primary function of protecting the boiler and generator from these tube leaks. For nuclear power plants, EPRI has suggested water chemistry requirements for both pressurized-water-reactors (PWR) (Tables 3 and 4) and boiling-water reactors (BWR) (Tables 5 and 6) (see also ⟶ Nuclear Technology).

Table 3. EPRI PWR Reactor feedwater/condensate chemistry guidelines, December 1996*

Control parameter	Frequency of measurement	Action levels		
		1	2	3
Hydrazine, µg/L	daily	< 20	–	–
Total iron, µg/L	weekly	> 5.0	–	–
Total copper, µg/L	weekly	> 5.0	–	–
Dissolved oxygen, µg/L	continuously	< 15, > 200	–	–

* Action levels are defined by EPRI in the guidelines in detail. In short: Level 1: return to these limits as soon as possible; Level 2: take immediate action, reduce power to obtain these limits within 8 hours; Level 3: shut down as quickly as safety allows.

Table 4. EPRI PWR Reactor blowdown chemistry guidelines, December 1996

Control parameter	Frequency of measurement	Action levels		
		1	2	3
Cation conductivity (25 °C), µS/cm	continuous		> 1	> 4
Sodium, µg/L	continuous	> 5	> 50	> 250
Chloride, µg/L	daily	> 10	> 50	> 250
Sulfate, µg/L	daily	> 10	> 50	> 250

Table 5. EPRI PWR Reactor water chemistry guidelines, December 1996

Control parameter	Frequency of measurement	Action levels		
		1	2	3
Conductivity, µS/cm	continuously	> 0.3	> 1.0	> 5.0
Chloride, µg/L	daily	> 5	> 20	> 100
Sulfate, µg/L	daily	> 5	> 20	> 100
Zinc, µg/L		> 5	> 20	> 100

Table 6. EPRI PWR reactor feedwater/condensate chemistry guidelines, December 1996 (with permission)

Control parameter	Frequency of measurement	Action levels		
		1	2	3
Feedwater conductivity, µS/cm	continuously	> 0.065	–	–
Condensate conductivity, µS/cm	daily	> 0.1	–	–
Feedwater total copper, µg/L	weekly	> 0.5	–	–
Feedwater total iron, µg/L	weekly	> 0.5	–	–
Feedwater dissolved oxygen, µg/L	continuously	< 15, > 200	–	–
Condensate dissolved oxygen, µg/L	continuously	< 15, > 200	–	–

If action level is exceeded, analyze samples again within 96 h. If levels are not met, proceed with Action Level 1 responses.

Ionic concentration specifications are also established for other applications. Table 7 presents water quality specifications for the pharmaceutical industry.

Table 7. USP XXIII water specifications

Control parameter	Control limit

Conductivity, µS/cm	1.25
TOC, µg/L	500
Microbial contamination (cfu/mL) *	< 100

* cfu = colony forming units

2.2. Organic Purity

The U.S.P. establishes the water quality for pharmaceutical applications in the USA. Other countries have similar standards. The U.S.P. water quality standards focus on the presence of organic compounds, expressed as TOC. Organic content of water primarily originates from the degradation of biological waste matter (humic type molecule structure) or microbiological sub-fragments. Table 7 lists ultrapure water quality specifications given in U.S.P. XXIII. Table 8 gives specifications for organics content of water used in microelectronics manufacture.

Table 8. Semiconductor UPW specifications for final filter water quality

Test	Attainable value	Acceptable value	Alert value	Critical value
Resistivity (25 °C), MΩ/cm	18.2	18.2	17.9	17.5
TOC offline, µg/L	< 10	20	40	80
TOC online, µg/L	< 1	< 2	5	10
THM, µg/L	< 2	< 5		
Number of particle per liter determined by SEM *				
0.1 – 0.2 µm	< 200	< 1000	< 2000	
0.2 – 0.5 µm	< 100	< 500	< 500	
> 0.5 µm	< 1	< 50	< 100	
Number of particle per liter determined by laser online counter				
0.05 – 0.1 µm	< 100	< 500		
0.1 – 0.2 µm	< 50	< 300		
0.2 – 0.3 µm	< 20	< 50		
0.3 – 0.5 µm	< 10	< 20		
< 0.5 µm	< 1	< 4		
Bacteria count per 100 mL				
By culture: 100 mL	< 1	< 6	25	> 25
1000 mL sample	< 0.1	< 1		
by EPI	< 10	< 30	> 50	> 100
Silica, µg/L				
Dissolved	< 0.2	< 1	> 3	> 10
Total	< 0.5	3	> 5	> 10
Residue batch, ppm	< 0.1	0.1	> 0.1	> 0.3

* SEM = Scanning electron microscopy.

2.3. Particulate Purity

Particles in ultrapure water may come from several sources. These include microbes or their components, fibers (typically from upstream membranes used to make ultrapure water), nonmetallic particles (typically precipitates or resulting from breakdown of materials of construction within the processing loop), and metallic particles (iron oxides, etc.). Table 8 lists the particle count specifications for microelectronics grade water. Of particular importance are the detection requirements as a function of sample method (on-line or grab sample) and the analytical method used.

Particles on microelectronic surfaces can physically damage transistors or short-circuit the flow of electrons and effectively disable an entire circuit. Particle control in power plants is related to crud removal, which can otherwise interfere with proper heat transfer. For nuclear plants where water streams have low-level radioactivity, particles become the largest potential source of radiation exposure to employees.

[Top of Page]

3. Technologies used for Ultrapure Water Processing

3.1. Ion Exchange Resins [3], [10], [12], [14], [19], [20], [23], [27], [35-41], [43], [44]

Ion exchange is required to obtain ultrapure water at the most stringent purity conditions, i.e., a resistivity > 18 MΩ/cm. Process schemes that include all other technologies discussed in this article, but exclude ion exchange can only reduce ionic concentrations to the µg/L) level (5 – 9 MΩ/cm for reverse osmosis, 16 – 17 MΩ/cm for electrodeionization. As the resins become loaded with ions, they release ions back into solution in accordance with the law of mass action. Expressed for cation exchange resin in the hydrogen form and an arbitrary cation i:

$$K_{\mathrm{H}}^{\mathrm{i}} = \left(\frac{C_{\mathrm{H}}}{q_{\mathrm{H}}}\right)^{z_{\mathrm{i}}} \left(\frac{q_{\mathrm{i}}}{C_{\mathrm{i}}}\right)^{z_{\mathrm{H}}}$$

where $K_{\mathrm{H}}^{\mathrm{i}}$ is the selectivity of the resin for ion i with respect to hydrogen, C_H and C_i are the liquid phase concentrations of cations and protons, q_i and q_H are the resin phase concentrations, and z_i and z_H are the respective valence.

The use of ion exchange resins is also a two-edged sword, since at ng/L levels of impurities the resin itself becomes a primary source of contaminants. These contaminants include residual chemicals from resin regeneration — primarily sodium and chloride or sulfate ions — and degradation products from the ion exchange resins themselves — sulfonates from the cationic exchange resins and functional amines from anionic exchange resins. In addition, ion exchange resins are an expected source of low levels of particles and bacteria.

3.1.1. *Mixed-Bed Ion Exchangers (see also* ⟶ Ion Exchangers – Ion-Exchange Resin Combinations, ⟶ Ion Exchangers – Mixed Beds, ⟶ *Water – Demineralization) [42], [45-50]*

A particular advantage of ion exchange resins is that both cationic and anionic resins can be used together to purify water. Cationic resins release hydrogen ions while anionic resins release hydroxide ions. The hydrogen and hydroxide ions combine on into water molecules. Mixed bed ion exchange is used to process boiler feedwater, make-up water, steam-cycle condensate or for final-stage polishing (removal of trace contaminants). With regard to boiler feedwater, make-up water, and applications with less stringent UWP requirements, fixed-bed demineralizers followed by mixed-bed polishing units may be all the water treatment used.

Mixed-bed polishers are used in high pressure (> 3.55 MPa) feedwater applications, where coordinated phosphate or equilibrium phosphate chemistry is used as the boiler water treatment for pH control to prevent corrosion. In water used in coal-fired and nuclear power plants, microelectronic sites, and pharmaceutical applications a first stage MBIE produces pure water for additional water treatment.

The use of mixed-bed polishers accomplishes several goals. First, they usually reduce the total electrolyte concentration in make-up or boiler feedwater to nearly 0.04 to 0.09 mg/L and silica from 0.01 to 0.05 mg/L. Second, mixed-bed ion exchange reduces sodium and silica leakage that occurs at the beginning and end of each operating cycle to provide a more consistent, uniform feedwater quality. Third, the use of mixed-bed polishing provides protection against breakthrough of the primary demineralizer units. Mixed-bed polishers typically require infrequent regeneration; some units operate for several years without regeneration.

Mixed-bed demineralizers are usually monitored by observing the pH, conductivity, silica and sodium content.

The pH of the water exiting any primary mixed-bed demineralizer is typically 6.5 to 7.5, depending on the temperature and water chemistry. Whenever the pH drifts from normal operating conditions, the first action is to verify the accuracy of the sensor. If the sensor is functional, ionic breakthrough is occurring and the mixed bed polisher or fixed bed demineralizer should be regenerated.

Similarly, the conductivity of the mixed-bed unit may rise when breakthrough of the fixed-bed units occurs. When an increase of the product water conductivity or specific conductance occurs, the bed should be regenerated if needed.

Silica concentration in the effluent is a critical factor with mixed-bed demineralizers that provide boiler feedwater make-up to high pressure boilers because silica can volatilize at low concentrations in boiler water when operating at ≥ 10.4 MPa. The volatilized silica then deposits on turbine blades as the pressure is reduced across the turbine. Therefore, on-line monitoring of silica exiting the mixed bed is desirable when the product water is used for high-pressure boiler make-up.

Sodium analyzers are used to determine the breakthrough of sodium in mixed-bed demineralizers because sodium is usually the weakest held cation, and an increase in sodium effluent concentration indicates breakthrough is about to occur.

Regeneration. The separation of the cation and anion exchange resin is the most critical step in mixed-bed ion exchange regeneration. If the resins are separated poorly, some cationic beads are exposed to caustic and some anionic beads are exposed to acid. This cross-contamination results in higher equilibrium leakage — the initial baseline effluent concentration — and shorter service life.

The relative terminal settling velocities of the cation and anion exchange resins govern the separation of the resins. The terminal settling velocity of a spherical particle is directly related to its density and diameter, and the resins are manufactured to maximize the difference in settling velocity. Separation of the cation and anion exchange resin is accomplished with a backwash of water at a fluid velocity that is lower than the terminal settling velocity of the cation resin which is usually less than that of the anionic resin.

Conventionally manufactured ion exchange resin has a variable particle diameter and is classified by sifting the resin with fine screen meshes. Developments in resin manufacture have led to nearly uniform particle size, which enhances the

separation of the resin types. However resins with uniform particle diameter may lead to operational complications. The increased settling velocity difference may lead to resin stratification before being returned to service.

Regeneration of a mixed-bed vessel requires cation and anion resin separation followed by the injection of acid and caustic to the cation and anion resin, respectively. The amount of regenerant chemical is determined by the volume of resin to be regenerated.

Regeneration intervals vary with the influent water quality and flow rate, regeneration of resins used in boiler feedwater at an ethylene plant may occur in 12 – 24 h increments, PWR nuclear regeneration cycles may typically be 30 d, while a polish mixed bed in a semiconductor plant may last a year or longer.

Typically two types of regeneration are performed for mixed beds

1. In-situ regeneration (Fig. 1) — An inert resin with a terminal settling velocity between those of the cation and anion resins is used occasionally. Inert resin is used continuously during the service and regeneration cycles. It can foul and attract organics onto the surface by electrostatic charge. After the resin is separated in the vessel, caustic is added to the top of the vessel while acid is added simultaneously in the bottom. The regenerant streams mix in the inert resin layer and are discharged. Advantages of in-situ regeneration include reduced equipment and labor costs. However, a higher proportion of resin will be cross-contaminated, leading to higher initial contaminant concentrations at the start of the service cycle.

Figure 1. Process flow for in-situ regeneration

2. External regeneration (Fig. 2) — In external regeneration the mixed resin is backwashed and sluiced to a separate vessel, where it is backwashed until complete separation is achieved, then one of the resin layers is transferred to another vessel the other one remains in the separation vessel. Both resins are regenerated and then mixed, rinsed, and placed back into service, The water purity observed after initiation of the service cycle depends heavily on the efficiency of resin separation. Advantages of external regeneration include higher separation efficiencies of cation and anion resin, leading to lower equilibrium leakage. Disadvantages include high equipment and labor costs.

Figure 2. Example process flow for external regeneration

3.1.2. *Homogeneous Beds*

Homogeneous beds may contain several different types of resin, such as strong acid cation, weak acid cation, strong base anion, or weak base anion exchange resin. Demineralizers usually consist of cation units followed by anion units. The simplest and most common configuration is a strong acid cation exchange bed followed by a strong base anion exchange bed.

The function of the *strong acid cation exchange unit* is to remove the soluble cations (Ca^{2+}, Mg^{2+}, K^{+}, Na^{+}, Ba^{2+}, Sr^{2+}) from the feedwater stream. Divalent cations are more strongly held than monovalent cations. Na^{+} is often the first cation to leak through the strong acid cation exchanger because it is the weakest bonded species. As the cations are removed from the water, the resin releases hydrogen ions.

The strong *base anion unit* removes anions such as sulfate, chloride, alkalinity, and silica from the water and releases hydroxide ions into the water. Alkalinity is a measure of the buffering capacity of water. It is often associated with carbonic acid, but may include weak electrolytes. Sometimes it is defined as the concentration of OH^{-} ions. Silica is the weakest held anion, and it is usually the first one to leak from a strong base anion unit.

Two-bed systems with strong acid cation and strong base anion exchange resins typically generate water with a total electrolyte concentration of 2 to 3 mg/L, and a silica concentration of approximately 0.02 to 0.1 mg/L. A summary is given in Table 9 of homogeneous and mixed-bed service water flow rates in various applications.

Table 9. Service water flow rates for various homogeneous and mixed-bed ion exchange resin applications

Bed type	Flow rate		
	Minimum	Service	Maximum
Cation exchange bed	3.7 m/h	4.9 m/h	7.2 m/h
Anion exchange bed	3.7 m/h	4.9 – 12.2 m/h	13.5 m/h
Boiler feedwater mixed bed		4.9 – 490 m/h	
Condensate polishing mixed bed		120 m/h	
Microelectronics polish vessel		60 m/h	

Demineralizers produce their best water quality when they are operated continuously, because the ions stratify in the resin bed depending on their respective valences and the corresponding selectivities during first of the resin. When demineralizers are shut down and subsequently restarted, the demineralized water eluting first usually contains an increased amount of impurities because the ions leak from the resin to the water and gradually diffuse throughout the length of the bed. Therefore, an additional rinse step is required before the demineralizer is put back into service.

Regeneration. Demineralizer trains consisting of strong acid cation exchange beds followed by strong base anion exchange beds are usually regenerated simultaneously and separately. Table 10 summarizes the similarities and differences of cation and anion resin regeneration.

Table 10. Ion exchange resin regeneration specifications

Regeneration specification	Cation exchange resin	Anion exchange resin
Regenerant	sulfuric acid (U.S. nuclear) hydrochloric acid (European nuclear, some semiconductor	sodium hydroxide (occasionally potassium hydroxide for environmental concerns)
Basic procedure	1. backwash 2. 2 % acid injection (for sulfuric acid only) 3. 4 % acid injection (10 % for hydrochloric acid) 4. slow rinse (≈ 2 bed volumes) 5. fast rinse	1. backwash 2. 4 % sodium hydroxide chemical injection 3. slow rinse (≈ 2 bed volumes) 4. fast rinse
Regenerant dosage	80 – 160 kg/m^3 (98 % H_2SO_4) 80 – 400 kg/m^3 (30 % HCl)	32 – 160 kg/m^3 (process dependent)
Regenerant flow rate	0.6 m/h	0.6 m/h

First, the *anion resin* is backwashed using cation product water. The backwash removes fines and any particulate material that has been filtered by the cation unit and settled on the top of the anion resin. This backwash step minimizes channeling that can cause short cation run lengths. In addition, the bed is re-classified and fines (e.g., fractured resin beads) are removed. Second, the anion unit is regenerated using 4 % aqueous sodium hydroxide solution. The dilution water must not contain Mg^{2+} or Ca^{2+} to prevent precipitation of these cations in the resin bed induced by the high pH.

The exchange capacity increases with increasing sodium hydroxide dosage and exposure time (or flow rate). Once the specified amount of sodium hydroxide is added to the dilution water, one to two bed volumes of dilution water are passed through the bed at the same flow rate. This is called the slow rinse and its purpose is to allow the entire regenerant dosage to pass through the bed at the designed flow rate. Next, the anion unit is fast rinsed at about 3.7 m/h. The purpose of the fast rinse is to remove the excess sodium hydroxide from the anion resin.

The most common acids used for regeneration of strong *acid cation resin* are sulfuric and hydrochloric acid. When sulfuric acid is employed as the regenerant, it is important to use a stepwise regenerant dosage, especially in water that contains a significant concentration of calcium ions to prevent calcium sulfate precipitation in the resin bed. When hydrochloric acid is used as the regenerant, a 10 % concentration is often maintained throughout the regeneration, precipitation of calcium

salts not occur.

3.2. Membranes (⟶ Water – Membrane Separation Processes in Water Treatment) [53-58]

Several membrane technologies are used in ultrapure water processing; reverse osmosis, nanofiltration, and ultrafiltration. The choice of membrane type depends on inlet water quality and required throughput. In general, the larger pore size ultrafiltration is used upstream in the process while RO is used to further treat processed water. Ultrafiltration helps minimize fouling of the more restrictive RO pores by not exposing them to a higher level of contaminants. If the feedwater does not produce excessive fouling of the RO, it is possible to use RO as an initial purification stage.

Nonporous membranes are available for specialized applications, such as pervaporation (⟶ Membranes and Membrane Separation Processes – Principle of Pervaporation). Water “dissolves” into the membrane structure and passes through by concentration flux. A vacuum on the permeate stream generates the concentration gradient.

3.2.1. *Reverse Osmosis [62-67]*

Several pressures and flow rates are normally monitored in a reverse osmosis system, and they are summarized in Table 11. In addition to these pressures and temperatures, the feed water temperature, the silt density index (SDI) and product and reject conductivities are monitored.

Perhaps the three most useful parameters for monitoring reverse osmosis operation are the normalized flow, percent salt rejection, and pressure drop (either the pressure drop across the individual element or that across the pressure vessel).

Table 11. Pressures and flow rates that should be monitored in a reverse osmosis system

Parameter	Location of sensor
Pressures	Pressure in cartridge filter
	Pressure after cartridge filter
	Pressure inlet into booster pump
	Feedwater booster pump discharge pressure
	Inlet feedwater pressure to each stage
	Brine (concentrate) pressure
	Permeate (product) pressure
Flow rates	Total feedwater flow rate
	Feedwater flow to each stage
	Permeate flow from each stage
	Total permeate flow
	Total brine flow

Normalized flow is used to monitor flow performance while correcting for change in water temperature. More water can pass through a reverse osmosis membrane when the water temperature is elevated because the pore size increases with increasing temperature.

Salt rejection is defined as the salt concentration in the feedwater minus the permeate concentration divided by the concentration in the feedwater. Salt rejection is usually expressed as a percentage.

The *pressure drop* per vessel should be limited to 500 kPa, and the pressure drop per element to 200 kPa. Excessive pressure drop can cause the membrane to compact and cause a permanent loss of flow. Periodic cleaning of the reverse osmosis membranes, or elements, should be done when the pressure drop begins to approach the limitations.

Reverse osmosis systems require cleaning when the normalized flow is reduced by 15 % or when the pressure drop per vessel increases to near the manufacturer's limits. This impaired performance can be due to particulate fouling, scale, organic fouling, and microbiological contamination.

Particulate fouling can occur when the pretreatment system does not remove the suspended solids present in the feedwater to the RO unit. Examples of particulate fouling include silt, particulate iron, and other corrosion products.

Scale occurs when salts exceed their solubility limit. This can occur as a result of many causes, including malfunction of pH control equipment a too high percent recovery of the RO unit, a too low addition or lose of antiscalant, or use of the wrong antiscalant.

Organic fouling occurs on RO membranes because the membrane surfaces are organic materials and have an affinity for other organic materials. Examples of common organic foulants include tannic acid and humic acid. Microbiological contamination can be either the slime of living organisms or the remains of dead organisms.

3.2.2. *Ultrafiltration and Nanofiltration [68-70], [81-88]*

Ultrafiltration and nanofiltration are similar in some respects to RO. The pore size of ultrafiltration and nanofiltration membranes is much larger, and they allow much higher flow rates. Both processes can be used effectively with UPW

applications as preliminary separation equipment. Nanofiltration can remove larger molecule, particulate, and divalent species: all but simple elemental ions and low molecular mass organics. The cutoff size is about 0.001 µm, compared to 0.01 µm for ultrafiltration and 0.0001 µm for RO. Both technologies can play a significant role in upstream processing by reducing the load on downstream equipment. Nanofiltration may reduce the hardness in the feedwater supply.

Pressure drop is the primary monitoring variable for adequate functioning of membranes. Increasing pressure drop is a sign that the membrane is accumulating mass on the surface. In some cases downstream water samples are filtered and examined by microscope. The presence of fibers is an indication of potential membrane failure. Exposure to ppm levels of oxidants, such as chlorine, can degrade cellulose acetate membranes to the point that they fail to meet UWP standards.

3.2.3. *Electrodeionization [71-79]*

Electrodeionization (EDI) is a relatively new separation technology that has found commercial application since the mid 1980s. EDI combines mixed-bed ion exchange with electrochemistry to split a feed stream into a product and concentrate stream.

As illustrated in Figure 3, the EDI unit works by placing a mixed-bed ion exchange resin between two special membranes that allow the migration of only cations or anions. Several mixed bed resin/membrane layers are placed between an anode and cathode, a direct current is applied between both electrodes. The influent is then passed through the mixed bed, where the cations migrate to the cathode through the cation membrane into the cation concentrate stream, while the anions migrate to the anode through the anion membrane into the anion concentrate stream. The concentrates are collected and led to the discharge effluent. Water is also electrolytically spit into H^+ and OH^- ions, thus providing a simultaneous regeneration mechanism for the cation and anion resin that does not require chemicals.

Figure 3. Electrodeionization unit configuration

Electrodeionization units have several advantages; such as continuous operation without regeneration, no regeneration chemicals, and relatively small power requirements. Disadvantages of EDI units were initially high capital costs, mechanical/electrical complications, low flow rates, and susceptibility to fouling. Current EDI technology has equalized the capital costs to that of a mixed-bed, and flow capacity has been increased to be comparable to mixed-bed ion exchange columns for some applications.

3.3. Adsorption — Activated Carbon Beds

Granular activated carbon beds can be used to remove chlorine from water before it enters either demineralizers or reverse osmosis systems. Chlorine removal by reaction with activated carbon is as follows [94]:

$$2\,Cl_2 + C + 2\,H_2O \rightarrow 4\,HCl + CO_2$$

6 kg of chlorine consume 1 kg of carbon. However, the use of activated carbon to remove chlorine from water streams is limited by the short life of carbon beds due to fouling. In addition, a carbon bed may be a microbiological growth site.

3.4. Degasification [95-97], [99]

Two types of degasification are prevalent in industry, forced draft and vacuum degasification.

Forced Draft Degasification (Decarbonator). Forced draft degasification is often used to remove carbon dioxide that may be physically dissolved in the water after the pH drop following a homogeneous cation exchange bed. A decarbonator is a column that has plastic packings at the top and a clear well underneath. The process water is spayed over the plastic packings, which increases the air – water interfacial area, and a low-pressure fan blows air from the bottom. The air strips the water of carbon dioxide.

Vacuum Degasification is used for the removal of dissolved oxygen and other gases. Process water is introduced into a tower that is under vacuum. The water approaches equilibrium with the low-pressure environment, liberating most dissolved gases into the vapor phase. The removal of dissolved oxygen is further advanced by the addition of pure nitrogen. The higher partial pressure of nitrogen leads to a lower partial pressure of oxygen and increases the driving force for oxygen to leave the liquid phase and enter the vapor phase.

3.5. Clarifiers and Chemical Precipitators

Clarifiers and chemical precipitation units are commonly used to pretreat water before its use as feedwater for demineralizers or RO.

Clarifiers are used to remove silt and other suspended solids from water. Cationic coagulants, sometimes used in conjunction with anion flocculants, are used to neutralize the silt and colloidal material present in many water supplies. Other clarifiers use coagulants such as alum to remove the suspended solids and adsorb the colloidal material.

Chemical precipitation units generally use lime in conjunction with organic or inorganic coagulants to remove suspended solids, colloidal material, and some of the dissolved solids in the water supply.

3.6. Chemical Chlorine Removal

Chlorine must be removed from feedwater before it enters ion exchange or RO systems to prevent oxidation of the ion exchange resin or RO membranes. Sodium sulfite, sodium bisulfite, sulfur dioxide, or calcium sulfite are among the chemicals that can be used for chlorine removal.

Sodium sulfite and sodium bisulfite react with chlorine according to:

$$Na_2SO_3 + Cl_2 + H_2O \rightarrow Na_2SO_4 + 2\,HCl$$

$$2\,NaHSO_3 + 2\,Cl_2 + 2\,H_2O \rightarrow Na_2SO_4 + 4\,HCl + H_2SO_4$$

Calcium sulfite is a granular material that slowly dissolves as it reacts with chlorine. The reaction is shown below:

$$CaSO_3 + Cl_2 + H_2O \rightarrow CaSO_4 + 2\,HCl$$

3.7. Ultraviolet Treatment [89-93]

Ultraviolet lamps serve two distinct purposes in ultrapure water manufacture; oxidizing organic compounds and sterilizing microbial contaminants. Oxidation of organic compounds requires 185 nm UV light in the presence of an oxidizing agent such as ozone or hydrogen peroxide. The compounds are oxidized to carbon dioxide and water. The carbon dioxide and remaining oxidizing agent may be removed downstream in a degasification unit. Microbial sterilization is typically accomplished with 254 nm UV radiation. The dead cell matter is removed downstream with a cartridge filter.

Some advantages of UV lamps include they are inexpensive, have relatively low maintenance requirements, and they destroy organic compounds instead of transferring them to another phase. The primary disadvantage of UV lights is their application is limited to pure water because turbidity and particulate matter affects the performance of the units.

3.8. Membrane Contactors [103-105]

Membrane contactors are useful for many gas – liquid and liquid – liquid separations. The principle of operation is analogous to that of a heat exchanger, except the primary driving force is the concentration difference between two fluids instead of temperature difference. Contaminants diffuse through a porous membrane from fluid A where they are present in high concentrations to another fluid B where the contaminant is not present.

Membrane contactors may be used instead of vacuum degasification towers for the removal of dissolved oxygen and other gases from ultrapure water. Figure 4 describes the mass transfer mechanism for transferring oxygen from water to the sweep gas. The contactor is typically cylindrical in shape, and has two inlets and outlets for the sweep gas and water. The sweep gas is typically pure nitrogen that may be under vacuum. Some applications require no dissolved nitrogen, in which case a vacuum is applied to the gas side of the membrane.

Figure 4. Mass transfer mechanism for membrane contactor

The advantages of membrane contactors include reduced space requirements and no mechanical parts. The disadvantages of membrane contactors include the possibility of particulate and organic fouling, cost, and maintenance of vacuum pumps if required.

3.9. Piping Materials, Gaskets [107-113]

Piping materials for ultrapure water vary upon the application. The nuclear industry uses stainless steel in the demineralizer make-up plant, where concentrations of contaminants are highest, and carbon steel in polisher vessels. The polishers tend to be rubber-lined, due to potential contact with regeneration chemicals. The semiconductor industry must use specialty plastics that do not shed particles and have low TOC leachables. Leachable TOC compounds include solvents or other organics within the polymer matrix that diffuse into solution. There are several plastics that may be used, such as poly(vinylidene fluoride) (PVDF), perfluoroalkoxypolymer (PFA) and poly(tetrafluoroethylene) (PFTE). Gasket materials must not generate particles; some common materials include teflon and silicone.

[Top of Page]

4. Analysis

4.1. Ion Chromatography [126-136]

Ion chromatography (IC) uses packed columns of ion exchange material to separate ionic species in a sample. As the separated peaks pass a conductivity detector, their relative concentrations are determined, as compared to the standard eluant concentration. With concentrator capabilities, IC can be used to detect ionic concentrations less than 1 ng/L.

Ion chromatography is the best method to determine a wide range of specific ion concentrations. IC can be used for either batch sampling or can be set up on-line. On-line IC typically reports lower readings than manually collected (grab)

samples. On-line sampling is only done when the severest specifications are required because of the expense and labor requirements of the IC. Even then, plants may forgo on-line IC analysis for other monitoring techniques supported by occasional IC grab samples.

4.2. pH Measurement

Monitoring the pH of ultrapure water is commonly done throughout the treatment plants, although at near neutral pH its value is somewhat limited. Although precision pH devices can measure pH to ± 0.01 this is not sufficient to represent accurate concentrations at ng/L levels. This can be seen by considering that for theoretically perfect water at pH of 7.00 0.1 µg/L H^+ and 1.7 µg/L OH^- present. However, UPW contaminant concentrations of interest are three to four orders of magnitude lower.

pH measurement is most applicable for power plants that add amines for corrosion control, for make-up water processing, for regeneration and rinse cycles, as an indicator of MBIE breakthrough, and plant concentration excursion incidents. However, since pH is such a basic water property and pH measurement relatively inexpensive, it is found on UPW lines as a normal monitoring tool.

4.3. Conductivity

Perhaps the most common method for determining the total ionic contaminants concentration in water is measuring the electrical conductivity.

At low concentrations, the conductance of water increases linearly with increasing concentration of ionic species.

Conductivity is temperature dependent, but most sensors have a temperature compensation method programmed in the electronics. The primary disadvantages of conductivity measurements are that only the total ionic concentration is estimated, specific ionic species are not measured, and conductivity sensors are generally ineffective detecting single digit ng/L ionic concentrations.

4.4. Ion-Selective Electrodes

Ion-selective electrodes can be used effectively in feed water and make-up water of demineralizers and RO units. However, for ultrapure flow streams ionic concentrations are below the detection limits of these devices currently. In addition, even at detectable parts-per-million ranges, some ionic species interfere with each other so that an accurate concentration of a specific ion may not be possible. A notable exception are sodium analyzers; current on-line sodium monitors are based upon a glass electrode that responds selectively to sodium. The hydrogen ion interference is minimized with the addition of ammonia or an organic amine such as diisopropylamine. Detection limits of 10 ng/L have been claimed; however, in practice the nominal detection limit varies from 50 – 100 ng/L.

4.5. Determination of Total Dissolved Solids

The quantity of total dissolved solids (TDS) is a measure of all solids, ionic or molecular, which remain after a sample is evaporated. This measurement is nonspecific in nature, and generally of advantage for the higher concentration streams within the UPW plant.

4.6. Determination of Total Organic Carbon [137-146]

A variety of total organic carbon (TOC), sometimes referred to as total oxidizable carbon analyzers are available in industry. Low-level analyzers operate by precisely recording the temperature and conductivity of a sample, oxidizing the sample to convert the organic compounds to carbon dioxide and water, and then measuring the conductivity of the sample again. The oxidation of simple hydrocarbons is described by the following generalized equation.

$$C_xH_y + [xy/4]O_2 \rightarrow xCO_2 + [y/4]H_2O$$

The change in conductivity is compared to a known calibration curve and the measurement is recorded (typically in ng C/g solution). The oxidation technique varies with the instrument; typically it is either a wet-chemistry or photocatalytic oxidation.

4.7. Particle Counters [25], [147-153]

Liquid particle counters operate by passing a small sample through a flow cell while a laser is focused on a photometric detector. The photometric detector sends a current proportional to the intensity of the laser to a recording device. When a particle passes through the flow cell, the particle scatters the laser light. The reduction of the measured intensity on the photometric detector is proportional to the effective diameter of the particle. The reduction in current is counted as a single particle, with a diameter determined by the change in the current.

The number of particle counts per given sample volume is the typical unit of measurement. Significant advances in on-line particle counters include increased sample flow rate and a particle diameter detection limit of 0.05 µm.

4.8. Colorimetric Analyzers for Silica and Phosphate [31], [32], [91], [92]

Silica detection is difficult with standard ion measurement techniques because silica is present in ionic, molecular, and particulate forms. The amount of ionic silica can be measured using a silicomolybdate/heteropoly acid blue colorimetric method. A sample of known volume is introduced in a cell and dosed with a molybdate reagent that reacts with available silica and phosphate to form molybdosilicic and molybdophosphoric acids. After several minutes, another acid (typically sulfuric acid or a proprietary mixture) is added to consume the monophosphoric acid. A photometric reference value is measured through the flow cell, and a complex reducing agent is added and allowed to react with the available molybdosilicic acid. The reduced molybdosilicic acid has an intense blue color and absorbs light at 810 nm. The intensities of the reference and sample values are compared to a calibration standard, and silica concentration is calculated from

Beer's Law. A similar technique may be applied to *phosphate measurement* at low levels; otherwise standard strip tests are available.

Methods for measuring the total concentration of silica include evaporation and digestion methods and the use of flameless atomic absorption.

4.9. Dissolved Oxygen Electrodes [95-98], [156]

Dissolved oxygen electrodes are an inexpensive, reliable tool of monitoring concentrations of dissolved oxygen in water. The electrodes are two noble metals (for example, silver and gold) immersed in an electrolyte solution. The electrodes are separated from the dectrolyte by a gas-permeable membrane.

The dissolved oxygen permeates across the membrane by partial pressure differences. An electric potential is applied across the electrode and reduces the oxygen inside the membrane. The resulting current is proportional to the oxygen concentration, and the value is calculated by comparing the current to a two-point calibration curve generated from zero oxygen and 100 % humidity air saturation. Sensors vary in quality; typical sensors may accurately measure oxygen concentrations as low as 0.5 µg/L to as high as 7 mg/L.

4.10. Capillary Electrophoresis

Capillary electrophoresis is a variation of electrophoresis (⟶ Electrophoresis – Capillary Zone Electrophoresis) where a sample passes down a capillary. The various components of the sample migrate differentially in an applied electric field and are thus separated. This is a technology with tremendous potential, but has not yet achieved concentration levels required for most ultrapure water application. The technology has been used to analyze anion concentrations to the single-digit µg/L levels. It has been evaluated on site after both power and microelectronics applications, but improved sensitivity is required for wide-spread ultrapure water use.

4.11. ORP Chlorine Analyzers

The oxidation-reduction potential (ORP measured in millivolts) can be used to control free chlorine or free halogen concentrations. There is no direct correlation between the ORP reading and the free chlorine content in water because of other impurities that contribute to the ORP value. One method of control is to use free chlorine test samples to determine the target ORP reading needed to provide the desired free chlorine concentration. The free chlorine concentration should then be tested using a chlorine test method to correlate its value with the ORP controller on a daily basis. ORP is normally measured in the make-up water loop of microelectronics plants.

4.12. Nonvolatile Residue Monitors [120-123]

Nonvolatile residue monitors (NRM) are used to measure dissolved inorganic material, including colloidal silica. The NRM is essentially a very sensitive resistivity monitor capable of measuring resistivity changes induced by charged and uncharged particles.

4.13. Use of On-line Analyzers and Manually Collected Samples

On-line analyzers routinely report lower concentrations than grab samples, because during collection of grab samples materials can be extracted from the sample bottle or atmospheric gases, primarily oxygen and carbon dioxide can be absorbed that interfere with the measurement. However, grab sampling is valuable, not because specific concentrations are observed, but because sampling notes changes in concentrations. The detected changes in baseline concentration measurements indicate problems as they occur.

[Top of Page]

5. Applications

5.1. Microelectronics Industry [167-174], [176-179], [181], [182]

Semiconductor Chip Manufacture (⟶ Semiconductors***).*** Semiconductor chips are manufactured using a complex procedure that chemically imprints a small, rectangular transistor pattern repeatedly on a circular disk, or wafer. After processing, the wafer is cut into rectangular chips, which are placed in a housing for attachment of pin-out connections to the silicon. Although the assembly of the chip requires some rinse water, wafer manufacturing consumes much larger quantities of ultrapure water.

The transistors are applied to the silicon wafer using a combination of film deposition, lithography, ion implantation, and chemical etching in a sequence that may contain more than 100 steps. During many of these steps, chemicals or residuals are rinsed from the wafer. Ultrapure water is used in many processing steps, but the major consumer of ultrapure water is chemical etching, where acids are washed from the wafer.

Since 1985, the number of transistors on processors has doubled nearly every 18 months. The increase in transistors is accomplished, in part, by reducing its line width (or size) from more than 1.0 µm to less than 0.2 µm. As the line width decreases, water purity requirements increase to reduce electrical shorting or physical destruction of the transistors during rinsing.

Semiconductor water systems are complex with many units in series. Figure 5 schematically illustrates the sequence of removal for ionic, organic, particulate, biological, and gaseous contaminants in a semiconductor ultrapure water system.

Figure 5. Sample UPW system for semiconductor applications

Fab = fabrication facility

The essential design considerations for semiconductor UPW systems include guaranteed water quality, cost, efficiency, and the prevention of damage to downstream units. The system is composed of three subsystems; the make-up system, the primary loop, and the polish loop.

The Make-Up System. The make-up system removes most contaminants from the inlet water. The primary objective of the make-up system is to maintain the level of the downstream RO storage tank. The primary units used in the make-up loop are:

1. The multimedia filter to remove large particulates, biological contaminants, and organics
2. Reverse osmosis (RO) membranes to remove approximately 99 % of ionic contaminants

A 10 – 20 µm cartridge filter may be used to prevent fouling of the ion exchange resin in the primary loop, and a heat exchanger may be added for temperature control. An additional chemical injection unit (not shown) may be placed before the RO membranes to prevent scaling on the concentrate side of the reverse osmosis units. Special piping materials are not usually required in the make-up system, typical materials of construction are low carbon steel, PVC, or polypropylene. Other purification units may be required in the primary loop if the source water has especially high levels of silica, organics, or biological contaminants.

Primary Loop. The water produced by the primary loop is typically ultrapure resistivity (> 18 MΩ) with respect to ionic contaminants, but organic, particulate, and biological contaminants may still be present. The primary loop serves two purposes: (1) to maintain the level of the downstream ultrapure water tanks, and (2) to dilute the incoming water from the make-up system. The primary loop flow rate is high enough that the water velocity prevents biological growth in the piping.

The main units in the primary loop are:

1. The RO product tank that stores the loop water and accepts make-up water,
2. 185 nm UV lamps, the radiation oxidizes organic contaminants to CO_2 and water.
3. Cation ion exchange resin column that removes metal and other cations,
4. Anion ion exchange resin column that removes halides and other anions,
5. Mixed-bed ion exchange column that removes most other ionic contaminants such as trace amounts of carbonate, silica, borate, and occasionally sodium.
6. 1.0 µm cartridge filter that removes particles that may be generated by the ion exchange resins.

The RO product tank is dimensioned such as to allow ample time to recover from a make-up system malfunction. The ion exchange beds are often chemically regenerated in-situ, i.e. an external resin transfer vessel is not required. The cation exchange bed should always be located upstream of the anion exchange bed. Should the anion exchange bed precede the cation exchange bed, the high pH of the anion effluent may cause metal hydroxide precipitation in the bed, which may foul the resin.

Other configurations of the primary loop are possible, e.g., the cation exchange bed may be removed if the inlet water contains no hardness, or both cation and anion exchange beds may be replaced with a second reverse osmosis stage or an electrodeionization unit. However, most configurations will retain a mixed-bed ion exchange column and a cartridge filter at the end of the primary loop.

Polish Loop. The water quality from the polish loop must meet factory specifications at all times. The key units of the polish loop are:

1. UWP storage tank, blanketed with nitrogen to prevent uptake of atmospheric oxygen and carbon dioxide. Ozone may be introduced in small quantities for biological sterilization and destruction of organics with the 185 nm UV lamps. The tank may be lined with specialty plastics or rubber, and the internals are composed of stainless steel or high quality, low TOC plastics.
2. 185 nm UV lamps, the radiation oxidizes trace organics to carbon dioxide and water. The ozone in the UPW tanks provides the oxygen for the reaction. The primary contaminants leaving the 185 nm UV radiation unit are trace amounts of salts, carbon dioxide, and dissolved gases.
3. Vacuum degasifiers, held at low vacuum to remove the remaining dissolved gases and some of the carbon dioxide. A nitrogen stream is used to vary the oxygen partial pressure in the vacuum and control the concentration of dissolved oxygen.
4. Mixed-bed ion exchange column, the final unit that removes ionic contaminants from the water. Its effluent usually contains only trace amounts of silica and borate. Concentrations of strong electrolytes are usually below detection limits, but the MBIE may release trace amounts of biological and particulate contaminants, especially after years of service.
5. 254 nm UV lamps used for sterilization of biological contaminants leaving the ion exchange columns. The UV

radiation kills almost any microbial contaminant, the dead cells are filtered off.

6. 0.04 µm cartridge filters to remove any particles or biological contaminants that may be generated by the mixed bed, or particles coming from materials of construction that pass through the beds. In 1999, 0.04 µm cartridge filters were the state of the practice. These final filters are positively charged to attract the — primarily — negatively charged particles. As a result, these filters can remove particles less than 0.04 µm in diameter.

The water in the polish loop is circulated continuously, the return flow rate is typically more than two-thirds the supply flow rate. The polish-loop construction materials are stainless steel for the piping from the UPW tank to the vacuum degasifier. After the degasifier, e.g., poly(vinylidene fluoride) (PVDF) piping is required to prevent ionic contamination from metal pipes, TOC leaching from polypropylene or postchlorinated poly(vinyl chloride) (CPVC) and oxygen diffusion from the air typical of other plastic piping. At room temperature, stainless steel pump internals and filter housings are required, while titanium may be used for high temperature applications. Gasket materials are often teflon or silicone.

Performance Issues with Adjacent Equipment. The location of units in the loops is important because removal of one contaminant often leads to generation of another that may be harmful downstream. Other considerations are the effects of a contaminated loop return line, or the accidental introduction of air or chemicals into the system. Some general guidelines are:

1. Reverse osmosis membranes and ion exchange resins may become fouled with particulate or biological matter. A filter should precede a reverse osmosis unit or train of ion exchange columns to prevent fouling.
2. Organic compounds can seriously foul ion exchange resins. Hence, UV lamps should precede the columns so the organic contaminants can be reduced to carbon dioxide. The vacuum degasifier assists in relieving the influx of carbonate to the ion-exchange beds by removing carbon dioxide.
3. Ion exchange resins typically generate particles from cracked resin beads, as well as biological contamination. Filters are needed to remove the particles before the stream is introduced into the loop.

5.2. Pharmaceutical Industry [175]

The U.S.P. defines six types of purified water (http://www.usp.org). These are:

1. Purified water
2. Water for injection
3. Bateriostatic water for injection
4. Sterile water for inhalation
5. Sterile water for injection
6. Sterile water for irrigation

In addition to U.S.P. other agencies or organizations have UPW specifications. Most developed countries have similar organizations that control water quality.

Typically the overall water quality of the water for pharmaceutical applications is less than that required for microelectronic applications, except with regard to microbes and pyrogens. An industrial process may deliver water with a resistivity > 18 MΩ less than 10 µg/L TOC, but no detectable bacteria.

The technologies and materials of construction for these processes are similar to those described for microelectronics UPW. Purification occurs primarily by a combination of RO and DI technologies. Water production rates are much lower than in other applications with total flow through a recirculating loop of a few hundred liters per minute.

5.3. Power Industry [1], [4], [5], [7], [11], [17], [166]

Power plants use ultrapure water to minimize erosion and corrosion of materials within the steam cycle. Water is processed in a make-up plant for all stations. During start-up, additional skid-mounted equipment may be brought to the site for increased capacity. Other applications of water treatment depend on the technology used at the specific plant. Condensate polishing is standard equipment for American nuclear power stations, but many fossil-fired power stations and French nuclear stations do not use condensate polishing within the steam cycle, although it may be required for start-up.

5.3.1. *Nuclear Power Plants*

In addition to make-up water processing, nuclear power plants have several water streams that may require treatment. Plants vary greatly because of different configurations, water chemistry goals, and their location (temperature, seasonal variation, and cooling water source). Some chemicals in the water are more damaging to the materials of construction than others. Consequently, control strategies minimize problem chemicals, such as oxygen and sulfate, at the expense of other chemicals.

The condensate of boiling-water reactors (BWRs) flows directly to the nuclear core (⟶ Nuclear Technology). The steam produced drives the turbines for power generation. The water needs to be very pure, and this generally prevents the addition of chemicals to control corrosion in the circuit. Some BWRs is added to the water to suppress water radiolysis, in others low levels of zinc are added to minimize the build up of cobalt-60 on metal surfaces in the reactor. Primary control strategies within a BWR are to minimize corrosion products, particles and sulfate: both limits are in the single digit µg/L range. To achieve this, full flow filtration and deep bed polishing of concentrates of BWR is employed. Condensate is fed to the steam generator, which maintains a constant-volume liquid level. The boil-up rate results in a concentration factor within the steam generator 100 times the condensate polisher effluent. For example, a 0.3 µg/L sulfate concentration results in a 30 µg/L concentration within the steam generator, which is excessive, and would exceed action limits at most plants and possibly cause corrosion. The reactor water is cleaned using a smaller mixed-bed ion exchange column connected in a recirculation loop with the reactor.

Impurity levels in BWR steam generator water are further controlled by the reactor water clean-up (RWCU) system. Approximately 1 % of the feed flow water is bled from the steam generator and passed through a heat exchanger and then a mixed bed before being returned to the steam generator. The function of the RWCU mixed bed is to remove silica, particulate impurities, sodium chloride, and sulfate. The resins are not regenerated but when exhausted they are transported to radioactive waste storage.

In pressurized water reactors (PWRs) steam generation occurs in a secondary loop, which allows the addition of chemicals, primarily amines, to the water (⟶ Nuclear Technology). The amine addition raises the pH and reduces the corrosion of ferrous metals in the steam – water circuit and hence the transport and deposition of corrosion debris.

Several mixed-bed ion exchange columns are connected in parallel to polish the full-flow of condensate; typically five to seven vessels are required. The control of corrosion debris particles in feed water to a BWR is important since these have high radioactive contamination that may lead to exposure of personnel. Mixed-bed ion exchange columns can function as a particle filter to a limited extent in some plants. However, current technology uses pleated or hollow fiber filters ahead of the mixed beds to remove particles and reduce the loading on the beds.

Beds used as a particle filter must be removed from service frequently for ultrasonic cleaning. This process destroys the concentration loading profile in the exchange column. The result is higher effluent concentrations from the bed with time then desired. Undisturbed beds may remain in service in excess of four years, roughly three to four times longer than beds undergoing regular ultrasonic cleaning.

5.3.2. *Fossil Fuel-Fired Plants*

The principles and methods described for nuclear systems also apply to fossil fuel-fired power plants, but to a lesser degree. Water purification requirements necessary to avoid erosion and corrosion are based on an economic analysis of the entire plant. The economic analysis is clear for the high cost of nuclear facilities, so that investment in water chemistry treatment, or in materials of construction is clearly favorable. However, the initial investment cost of fossil plants is far less. In addition, when maintenance in required, there is no concern for exposure to radioactivity, so maintenance costs are relatively less as well. These factors make condensate polishing less common for fossil-fired plants, although EPRI guidelines still indicate an economic advantage for polishers.

5.4. Chemical Industry

The chemical industry uses ultrapure water primarily for two purposes, boiler feedwater make-up and process water.

5.4.1. *Boiler Feedwater Make-up*

Demineralized water, or an equivalent, is often used for boiler feedwater when the boiler operating pressure is ≥ 6.3 MPa. There are instances when ultrapure water is used as boiler feedwater make-up for boilers operating at 4.24 MPa. Reasons for using ultrapure water for boiler feedwater include:

1. Increasing the cycles of concentration, thus conserving water and energy
2. Reducing the likelihood of scale deposits in the boiler system
3. Systems where the steam is used to drive turbines
4. Systems where the steam is superheated
5. Systems where the steam is injected into a process stream

The acceptable concentration of water impurities decrease as the boiler operating pressure increases. Table 12 describes the maximum allowable conductance, silica concentration, and alkalinity in boiler water as a function of pressure.

Table 12. Maximum silica, alkalinity, and conductance in boiler feedwater as a function of pressure

Pressure, kPa	Total silica concentration, mg/L	Alkalinity, mg/L	Specific conductance, µS/cm
4.240	40	250	2500
5.270	30	200	2000
6.300	20	150	1500
7.000	8	100	1000
10.450	2	none allowed	150
13.900	none allowed	none allowed	100

5.4.2. *Process Water*

There are some applications for ultrapure water in the chemical industry. In most of the cases, specific substances must be kept out of the system to avoid contamination. Uses of ultrapure water in process water applications include the following:

1. Metals rinsing before painting
2. Metals fabrication
3. Process water for metals refining operation
4. Applications where stainless steel will be used at temperatures exceeding 60 °C

5. Process water for pharmaceutical applications

Ultrapure water is often used when one or more of the following common water impurities need to be minimized: calcium, magnesium, sodium, potassium, iron, copper, manganese, chloride, sulfate, silica, alkalinity.

[Top of Page]

6. Future Developments

Ultrapure water quality will continue to be driven by the microelectronics industry. Decreasing line width on semiconductors as computer memory expands and a decrease in processing time dictate these requirements. A common theme of discussion in the industry is that if they can measure contaminants in the water then they should be removed.

Alternatively, chip yield (percentage of working microchips as a fraction of total chips made) should be correlated with water chemistry, and water purity requirements should be established to meet these yield requirements. When taking this approach, added cost to achieve unneeded water quality may be minimized. If sufficient chip yield is achieved with ng/L water quality, then the need for pg/L concentration targets is not justified.

As microelectronic manufacture drives the development of ion exchange and membrane products, all other ultrapure water applications benefit. However, resin and membrane manufacturers must address some specific needs. There is a need for resins that set free a smaller amount of sulfonates, sulfates, and particles. Development of membranes with longer service life will continue, while allowing higher throughput with reduced contaminant permeation. EDI research will continue, and the role of this technology will likely increase. Analytical equipment will be continuously improved with more accurate and lower detection limits. However, the acceptance of this equipment will depend on its cost – benefit ratio.

As the separation technologies increase in performance and asymptotically approach the zero contaminant level, the cost of water production becomes the major design issue; ultrapure water is a utility cost and its minimization leads to greater profits. Waste minimization is also a significant design factor for semiconductor manufacturers. Several UPW plant designs exist using evaporators and crystallizers to attain near-zero-liquid-discharge (NZLD), which allows greater flexibility for site selection because the make-up water requirements are much smaller and environmental impact is significantly decreased.

1. Introduction

Bioremediation designates soil remediation methods, which make use of the natural metabolic potential of microorganisms to degrade organic contaminants. In order to achieve maximum degradation rates optimal environmental conditions (provision of nutrients, moisture, temperature) must be set. The contaminated soil to be cleaned is either excavated or, if this is not possible, treated by in-situ methods.

The development of biological soil remediation, from initial tests on a small scale to cleaning large quantities of soil, took place over a period of about 15 years. Three large phases can be distinguished:

Phase 1. At the beginning exclusively static treatment of the contaminated soil was carried out. After technical preparation of the soil (sorting, crushing, addition of nutrients, homogenization) open bio-beds exposed to the weather were laid out (Fig. 1). The remediation periods for degradation of hydrocarbons were approximately 1 – 2 years.

Phase 2. In the next step the bio-beds were provided with covers to become independent of the weather (Fig. 2). Furthermore, shorter degradation periods could be achieved during the warm season due to the increased temperature under the cover. In addition, the remediation process was accelerated by regular turning of the contaminated soil.

Phase 3. On-site biological soil remediation was further optimized by using large tents instead of low covers. In this way, large quantities of soil could be cleaned and larger turning machines could be employed. Further development led to the building of stationary soil remediation plants in which more than over 100 000 t of contaminated soil are being cleaned today. In 1999, the throughput of biological soil remediation plants in Germany was around 2.7 times higher than that of soil washing plants [4].

The scope of application of the virtually natural remediation technology now encompasses a wide range of contaminants. In addition to the "customary" damage caused by petroleum contamination, polycyclic aromatic hydrocarbons (PAH) [5–7], highly volatile chlorinated hydrocarbons (CHC) [8], explosives such as trinitrotoluol (TNT) [9] and other organic contaminants can be detoxified by biological treatment.

2. Microbiology

Microorganisms are usually unicellular organisms with small dimensions and a simple cell structure. Microorganisms include algae, fungi and protozoa, which can be classified as *eukaryotes*, as well as *bacteria* in a restricted sense and *archaebacteria* (*prokaryotes*), whose cell structure differs considerably from that of all other organisms. For biological remediation methods the decomposition induced by bacteria and fungi in the soil is of primary importance.

Because of their special genetic structure *bacteria* are able to change their genetic charac-

Figure 2. Biological soil remediation with closed bio-bed

ter abruptly, i.e., to mutate. Their spontaneous "shifts in genetic characteristics" and very short reproduction cycles impart these microorganisms a significant adaptability to their surroundings. In this way "nutrients" that previously could not be utilized may also be degraded microbially after a while.

Fungi occur in a wide variety of forms, ranging from microscopically small, unicellular organisms to visible fungi → Fungicides, Agricultural. Since fungi do not have photosynthetic pigments as green plants, they have to feed on organic material. Most fungi grow under aerobic conditions and obtain energy by decomposition of organic substances.

Wood-degrading "white rot" fungi, which belong to the group of basidiomycetes, are of special importance for biological remediation methods. These fungi, such as *Trametes versicolor* (Fig. 3), *Pleurotes ostreatus* and *Phanerochaete*

chrysosporium, are able to cleave the chemical structure of lignin with the help of special enzymes.

Figure 3. The "white rot" fungus *Trametes versicolor* [10]

Tar oils, i.e., PAH, which frequently occur as soil contaminants in the ground of gas works, coking plants, and companies that process tar products, have a similar chemical structure to lignin. These substances are often difficult to decompose by bacteria due to their high chemical stability and low solubility in water. White rot fungi have been successfully used several times for biodegradation of PAH with lower molecular mass thanks to the similarity in the chemical structure of the substrates [11–13]. However, high-molecular PAHs are more or less nondegradable. Furthermore, the successful biological decomposition of tar oil is highly dependent on the soil structure and the concentration of organic carbon.

3. Fundamentals of Biodegradation Processes

Many microorganisms are able to decompose not only biologically generated substances, e.g., petroleum hydrocarbons, but also synthetic organic substances. By virtue of the high degree of flexibility with respect to metabolism and the adaptability of a large number of bacteria and fungi, the scope of microbial degradation theoretically encompasses all groups of organic contaminant groups. An analysis of examined contaminated sites showed that most types of contamination are of organic nature (Fig. 4) and can thus be biologically degraded in theory.

The organic substance can be decomposed completely (mineralized) or transformed and thus be used to build up microbial biomass. Furthermore, the organic molecules can be recycled to the natural carbon store in the soil (humic matter) depending on the degree of their degradability. Delayed mineralization of the organic substance then takes place in the very slow process of humic metabolism.

The possibility of microbial degradation has been verified for a great number of environmental contaminants by means of laboratory and field tests. For many aliphatic and aromatic mineral oil hydrocarbons the degradation by bacteria and the regulation mechanisms of this degradation have already been elucidated completely.

One of the most important condition for the successful degradation of aromatic hydrocarbons is the availability of oxygen, which must be introduced at two steps.

1) The pathway from, e.g., benzene to pyrocatechol requires oxygen to "produce" this more water-soluble substance due to the introduction of two new OH groups (see Fig. 5)
2) The aromatic ring is cleaved only in the presence of oxygen

After the cleavage and the formation of intermediate products the tricarboxylic acid cycle splits the metabolites into low molecular organic acids such as acetic or succinic acid. The final products are carbon dioxide and water. (Fig. 5).

The ability to degrade hydrocarbons is widespread among bacteria and yeasts, but occurs particularly frequently among representatives of the genera *Pseudomonas, Alcaligenes* and *Acinetobacter*. Important HC-degrading bacteria are listed below [14]:

Acinetobacter
Pseudomonas
Leucothrix
Alcaligenes
Spirillium
Micromonospora
Bacillus
Thermomicrobium
Mycococcus
Corynebacterium
Xanthomonas
Klebsiella
Actinomycetes
Sphaerotilus
Micrococcus

Figure 4. Spectrum of contaminants at contaminated sites
CHC = chlorinated hydrocarbons; HC = hydrocarbons; PAH = polycyclic aromatic hydrocarbons

Arthrobacter
Streptomyces
Mycobacterium
Brevibacterium
Vibrio
Nocardia

Figure 5. Schematic diagram of degradation of aromatic hydrocarbons

Important HC-degrading fungi and yeasts include [14]:

Aspergillus
Phoma
Gliocladium
Beauveria
Scopulariopsis
Hansenula
Citromyces
Rhodotorula
Mortierella
Debaryomyces
Torula
Penicillium
Fusarium
Aureobasidium
Scolecobasidium
Graphium
Candida
Sporobolomyces
Monilia
Chladosporidium
Tolypocladium
Paecilomyces
Endomyces
Torolopsis

These phyla could be isolated from a wide variety of ecosystems (seawater and fresh water, soil, sediment) [15]. The microorganisms additionally showed extremely high degradation rates for polycyclic cycloalkanes and aromatics. In ecosystems that have not yet been in contact with petroleum contaminations, petroleum petroleum-decomposing phyla represent only a small proportion of the microbial population whereas they can make up to 100 % of the microorganisms in contaminated areas. The percentage of organisms that degrade petroleum hydrocarbons can thus be regarded as a sensitive

biological indicator for hydrocarbon contaminations [15].

Some difficultly degradable compounds – high molecular condensed aromatics, highly chlorinated organics, dioxins, dibenzofurans – can be partially microbially degraded, predominantly under special laboratory conditions [6]. These tests have shown that the limits of biological decontamination processes are not determined by the metabolic abilities of the bacteria, but to a great degree by the environmental conditions (abiotic factors).

Generally, microbiological remediation methods make use of the natural metabolic potential of microorganisms. The soil can be viewed as a biological fixed-bed reactor with a large internal surface. Microbial metabolic activities are fostered by optimal provision of mineral nutrients, moisture, and temperature conditions.

The supply of microorganisms with oxygen is ensured by introduction of hydrogen peroxide and ozone or by mechanically working the soil (turning, ploughing, tilling). In addition, mineral nutrients (especially phosphorus and nitrogen) have to be supplied. Nitrogen and phosphorus must be added in the correct relation to one another and to the concentration of organic carbon in order to provide for extensive mineralization of the contaminants. An optimal pH value (for bacteria in a slightly alkaline range of 7.8 – 8) can be achieved by addition of lime. Another prerequisite for a high degradation rate is a uniform distribution of contaminants along with good permeability of the soil, which is achieved in remediation measures through preparation of the excavated soil (sorting, homogenization).

4. Processes

Treatment of contaminated soil is either carried out locally (on-site) or in soil remediation plants (off-site). If the contaminated soil cannot be excavated, in-situ methods are applied (see Fig. 6).

4.1. On-Site Methods

Bio-Beds. Biological soil remediation can be carried out on-site primarily in regeneration heaps/bio-beds/biopiles or in bioreactors. The schematic process is presented in Figure 7. After excavation of the soil the material is homogenized to ensure:

Uniform distribution of contamination
Loose soil structure
Good aeration of the soil, and
Optimal availability of contaminants for the microorganisms

During homogenization various additives, such as bark mulch, straw or compost material are added, according to the need for structural improvement.

After pretreatment the actual microbiological degradation takes place. It is of crucial importance that the microorganisms working and reproducing in the soil are supplied with sufficient oxygen. Mainly biodegradation is started with a *dry rotting* process set up without base seal. In the dry rotting process air is either introduced through regular turning of the soil or through aeration pipes running inside the beds. In the sprinkler method the bio-beds are equipped with a sprinkler device and appropriate sealing at the bottom. In the case of the sprinkler method the oxygen reaches the bacteria via the water.

Environmental conditions (e.g. water content, temperature, pH value) are regularly monitored in a laboratory.

Bioreactors. In addition to the heap methods, treatment in closed bioreactors is being increasingly implemented for degradation of more complex contaminants. Under completely controllable conditions, the following objectives are achieved in closed bioreactors:

Acceleration of contaminant degradation
Better bioavailability of the contaminants
Better contact between contaminants and bacteria, and
Application of biodegradation to new substance classes

In bioreactors chlorinated hydrocarbons [16] or TNT can be detoxified by biodegradation, transformation, or through an alternation between anaerobic and aerobic conditions.

Since bioreactors are very complex and costly devices, their use only makes sense if no other methods are available.

Figure 6. Microbiological remediation methods

Figure 7. Schematic diagram of process for biological soil remediation

4.2. In-Situ Methods

In-situ methods are useful in the following cases:

Buildings, tanks, and roads on the ground must not be torn down. Consequently soil excavation is not possible.

The contamination has spread vertically and horizontally to such an extent that soil excavation is not sensible in economic and technical terms.

The most important prerequisite for in-situ remediation is a good permeability of the soil because the required substrates such as oxygen, adapted microorganisms, and nutrients must reach the contaminated area via water as the transport medium. As a rule, particularly in deeper soil layers the ambient conditions are substantially improved by setting up a rinsing circulation system. Furthermore, a practical arrangement of suction and injection wells ensures

that the treatment is limited to the contaminated grounds. Any undesired discharge of contaminants and bacteria to the surrounding area is thus avoided.

In addition to degradation in the soil itself, the installed water circuit also washes part of the contaminants out of the ground. Suitable measures, such as biological or chemical – physical water purification, further lower the contaminants concentration in the circulated water (Fig. 8).

4.3. Off-Site Methods

In the 1990s, soil remediation activities have extensively shifted from on-site methods at the respective contaminated sites to off-site treatment in stationary soil treatment plants (→ Soil, Chap. 7.1.2.1.).

Off-site the throughput of the soil remediation plants (total approximately 3.2×10^6 t/a), are dominated by biological methods. With approx. 2.3×10^6 t/a biological technology has surpassed soil washing by 1.4×10^6 t/a. Thermal plants reported a throughput of around 130 000 t/a [4].

In principle, the procedure and treatment in a biological soil remediation plant are comparable with on-site remediation.

5. Use of the Cleaned Soil

Soil that is cleaned by on-site remediation or at a stationary plant is again subjected to a meticulous chemical and biological examination. Besides the verification that the contaminations in the soil are below the legal threshold limits, a number of other quality characteristics are determined, including:

Grain mix
Humus content
Water storage capacity
Soil biology
Plant compatibility
Absence of weeds and
Hygienic safety

The results are important prerequisites for recycling of the cleaned soil. In addition, supporting toxicity tests are carried out with luminous bacteria, for example.

The entire process from reception of the cleaned soil to its transport to the site of reuse is constantly monitored and controlled by biological – chemical laboratories to ensure that no hazardous residual substances remain in the soil and the stipulated limit values are complied with.

Further biological treatment procedures in conjunction with on-site remediation are connected with cultivation measures at the respective sites. In a 30 – 40 cm thick layer the cleaned soil is placed on the fallow areas created where it is used as new topsoil. The new soil has a higher biological activity and an increased humus concentration than the usually depleted industrial fallow areas.

On the basis of planting measures suitable for the soil and balanced fertilization, the existing microorganisms can continue to decompose hydrocarbon products in the cleaned soil. In this way a residual concentration of 319 mg/kg could be minimized to less than 100 mg/kg.

This clearly indicates that contaminant degradation is not yet finished after successful conclusion of biological remediation. By restoration of the ecological functions of the soil, its fertility can be enhanced and the degradation of residual concentrations of contaminats can be reactivated. This degradation is possible up to a level that corresponds to the natural soil contents.

6. Case Examples

6.1. Remediation of a Tank Farm

For several decades gasoline, diesel fuel, and heating oil were handled at a tank farm more than 3000 m^3 in size in Saalfelden, Austria. Due to leakage, particularly as a result of corrosion, as well as during loading and unloading operations, mineral oil accumulated in the soil. In the course of investigations on the grounds, a vertical spread of contamination extending to approx. 12 m below ground level was determined. Analyses of soil samples showed a maximum concentration of hydrocarbons of 14 100 mg/kg. Since the contamination had penetrated down to the groundwater, the groundwater level was lowered for excavation of the soil masses.

Figure 8. Microbiological and hydraulic in-situ remediation. According to [17].

Initial estimates indicated around 20 000 t of contaminated soil. In the course of excavation work, however, it turned out that the contaminated area was significantly larger. A total of about 110 000 t of soil were treated by means of microbiological methods. The total length of the large tents in which the soil was cleaned was over 1500 m. The conducted biotests indicated an expected degradation period of ca. 6 – 8 months, which was also confirmed in practice (Fig. 9). After remediation the entire soil material was used to refill the construction pit [18].

Figure 9. Degradation graph

6.2. Remediation of Soil Contaminated with TNT

A new humification method has been developed for the biological treatment of soil that is contaminated with highly toxic nitroaromatics such as TNT. This method can transform these compounds into nontoxic ones under sequentially reducing and oxidative ambient conditions [19], [20]. This is achieved by means of:

1) Targeted addition of specially combined, preconditioned substrates, and
2) Optimal mechanical soil tilling that is adapted to the respective degradation phases.

During treatment a gradual reduction of TNT takes place, resulting in the formation of triaminotoluene (TAT) as the final product (Fig. 10). Triaminotoluene is irreversibly immobilized in the humus matrix and thus detoxified. A first large-scale test, in which approx. 70 t of contaminated soil were treated, demonstrated the efficiency of the method.

Prior to the tests the soil was excavated on the grounds of a former explosives factory, screened to a grain size of 60 mm (the oversize portion was rejected), homogenized, and stored in closed transport containers. In a treatment tent the soil was intensively mixed with the substrate (consisting of several natural organic components). A total of 36 wt % substrate was added to the soil. The arrangement of the construction site is shown in Figure 11.

Figure 10. Transformation path of TNT

Figure 11. Arrangement of an on-site TNT treatment plant

The contaminant concentration was analyzed in an on-site laboratory. The original soil displayed a medium contamination with nitroaromatics of 1126 mg/kg. The initial contamination after addition of the substrate mix was around 699 mg/kg. The concentration of nitroaromatics during the first 14 days was within the detection limit range (0.5 mg/kg). On the 14th, 16th, and 18th test day nitroaromatics could still be detected in individual mix samples. In the subsequent investigations no contamination was detected up to the end of the test (86th day). Similar results are reported in [9], [20], [21]. On the basis of the positive results of the first test batch, the cleaned soil was placed back on the factory grounds.

1. Introduction

Since early antiquity, the deterioration of building stones has been a well-known problem in the preservation of our cultural heritage. The Great Sphinx in Giza, which had been covered by sand for centuries, was excavated and restored for the first time by THUTMOSIS IV (1400 B.C.). The vestiges of this intervention, revealing several layers of square stones which had been put in place to repair the deteriorated surface of the body of the Sphinx, can still be seen today. The cathedral stonemasons workshop – some of them existing since the erection of the cathedral – demonstrate the necessity of steady maintenance and repair. According to the opinion of most scientists, the rate of damage to historical monuments has increased exponentially since the beginning of industrialization in the 1800s [1], [2]. In fact, many photographs taken around 1900 seem to confirm the enormous progress of deterioration in monuments in the past 100 years (Fig. 1).

However, the state of many monuments was already alarming in the 1800s. Gypsum copies which were produced from the sculptures of the Fürstenportal at Bamberg cathedral between 1904 and 1906 clearly demonstrate that at the turn of the century the degree of deterioration of the 24 figures was almost the same as in 1990 (Fig. 2).

Because there is only insufficient documentation on the state of monuments, our knowledge is still too limited to decide whether increased deterioration has taken place during the course of the 1900s. In many cases the destruction cannot be attributed to air pollution effects alone, but is also the result of defective or inappropriate maintenance.

Historical monuments reflect the development of air pollution during their life history. The damages that we observe today are the consequences of a long-term accumulation of damaging substances and growing damage factors. Exposure programs started during the past 25 years show a correlation between material loss and intensity of air pollution [3–8]. Several authors estimated damage functions for SO_2 and H^+, especially for calcareous stones [3], [9–12]. A synergistic effect of SO_2 and NO_x on the damage rate was found [13], [14]. The susceptibility of different stones to various gaseous air pollutants becomes evident in the different deposition rates for SO_2, NH_4^+, and NO_x, which depend on the physical and chemical properties and the

moisture content of the stone surface [15–19]. Both parameters are very much influenced by the formation of biofilms, which enhance the deposition of particulate matter and gaseous pollutants [20–22]. Further information regarding the correlation of air pollution and stone deterioration can be found in [23], [24].

Scientific investigation into the deterioration and conservation of building stones began in the 1800s and depended on the progress in chemical research. In particular, conservation was mainly concerned with the preservation of the many works of art that entered European museums after having been excavated in antique sites around the Mediterranean Sea [25]. Comprehensive bibliographies on the use, deterioration, and conservation of natural stone were presented in [26], [27]. An interesting account on former treatments in England is given in [28], which concluded that most conservation products had failed or showed neither positive or negative effects. Like today, the products that were used for stone conservation were primarily developed for other purposes and then recommended for conservation in order to open up additional sales. The list of historic stone-conservation products is quite limited and comprises materials which were well-known since antiquity or invented in the 1800s. Probably the most complete compilation of commercially available stone conservation products can be found in [29], in which producers, trade names, and chemical compositions of the products are described. In the following sections the most important methods and materials for stone conservation are described.

Figure 2. Three apostles of the Fürstenportal at Bamberg cathedral in 1990.

2. Traditional Stone-Conservation Products

2.1. Limewater and Lime Wash

Limewater is a saturated solution of $Ca(OH)_2$. It contains 0.18 g of dissolved $Ca(OH)_2$ per liter. Brittle stones are soaked with limewater several times, a procedure that takes weeks or even months. The idea is to replace the dissolved binding cement of stones by introducing new calcium carbonate according to the reaction

$$Ca(OH)_2 + CO_2 \longrightarrow CaCO_3 + H_2O$$

However, a strengthening effect has never been proved, because the total amount of deposited $CaCO_3$ is very small and the crystals are mainly formed near the surface where the $Ca(OH)_2$ can react with atmospheric CO_2. In fact, treatment with limewater has rather negative effects due to the enormous quantities of water that are applied to the stone. In addition, the alkalinity of the limewater increases the rate of SO_2 deposition, so that all of the $CaCO_3$ formed is converted into gypsum within a very short time.

Lime washes are thin layers of very fine lime mortar. Their thickness is on the order of a few millimeters and should not exceed 5 mm. The purpose is to protect the original stone surface from incident rain and air pollutants by means of a sacrificial layer. When the sacrificial layer is worn down it can be renewed by a new layer. The method has attracted increasing interest in several European countries, especially regarding the criteria of compatibility and re-treatability [30]. It is also quite popular in the United Kingdom, where most of the historic monuments and cathedrals are built of oolitic limestones, so that the use of lime-wash mortars has a greater tradition than elsewhere [31]. One of the most important examples of applying lime washes is the treatment of the figures in the west facade of Wells cathedral that was carried out during the restoration of the whole facade in the 1980s. The lime wash, which has the consistency of a putty, is rubbed into surface cracks and delaminating flakes with soft brushes, thus stabilizing loose surface parts.

Tests on sample areas on pinnacles of Cologne cathedral showed an insufficient durability of the lime washes, which were completely weathered after only one year of exposure [32]. Results obtained in Austria demonstrate that in order to achieve the desired effectiveness lime washes must be modified with polymer dispersions [30] or even hydrophobized, so that their properties can no longer be strictly distinguished from those of dispersion paints.

2.2. Linseed Oil

Linseed oil, a mixture of oleic, linoleic, and linolenic acids, (→ Fats and Fatty Oils, Chap. 13.2.4.3.) belongs to the so called drying oils (→ Drying Oils and Related Products). Drying occurs through reaction of the C=C double bonds to form a polymer.

Linseed oil is commercially available in different grades according to the degree of refining. Stand Oil is produced by heating linseed oil in the absence of air in closed vessels (→ Drying Oils and Related Products, Chap. 8.2.). By this process, several of the reactive double bonds react with each other, thus forming larger molecular units. The reactivity and ability to form a polymer network decreases. The drying is enhanced by lead compounds. For this reason linseed oil is the typical binder in oil paints and in particular in lead white paints.

Linseed oil has been in use for stone preservation for centuries, probably even since antiquity. It was the main constituent of many products that were on the market from the 1800s up to ca. 1950 [29]. It has been applied to limestones and porous sandstones. Ref. [33] underlines both its strengthening and hydrophobic effect, moreover arguing that even its swelling due to the action of moisture could be advantageous because further penetration of rainwater would be eliminated. However, its insufficient penetration depth, discoloration, and steadily increasing brittleness together with decreasing hydrophobic effectiveness are detrimental to its use.

2.3. Waxes

For centuries, natural waxes have been used for protecting and polishing susceptible stone surfaces. The most frequently used wax is bees wax which is available in different grades with increasing degrees of refinement. It is still applied

today, e.g., for polishing marble tombstones on the inner and outer walls of churches. Bees wax possesses the advantage of not becoming brittle even after decades, but its stickiness causes ugly dirt depositions, especially in the open air. Modern stone-care waxes are based on various paraffins and are sold in dissolved (organic solvents) or dispersed (in water) state.

2.4. Fluorosilicates

Hexafluorosilicate salts of the cations Mg, Al, Zn, Pb, Cu, Cr, Fe, ammonium ion, and alkali metals are still applied, mainly to improve the density of pores and the chemical resistance of concrete. The effect is apparently based on the deposition of amorphous silica gel. In the literature, two different reaction varieties can be found which describe the chemical reactions in case of concrete or sandstone.

Concrete:

$$2\,Ca(OH)_2 + MgSiF_6 \longrightarrow 2\,CaF_2 + MgF_2 + SiO_2 + 2\,H_2O$$

Sandstone and limestone:

$$2\,CaCO_3 + MgSiF_6 \longrightarrow 2\,CaF_2 + MgF_2 + SiO_2 + 2\,CO_2$$

Although the formation of amorphous silica is not doubted, both reactions are tentative because the reaction products CaF_2 and MgF_2 were never clearly determined. An effect can only be expected for limestones or calcareous sandstone.

Mg- and Zn-fluorosilicates were very wide spread after their synthesis in 1883 by Kessler. Whereas ref. [25] favors their application for limestones, ref. [33] objects that the strengthening would be restricted to the very surface and could yield negative results in the long run. Because the salts are strongly acidic, the same discolorations can occur as with the use of hydro fluoric acid.

2.5. Water Glass

Several patents have been issued for the synthesis and production of stone-conservation products based on water glass [26]. Early water glass paints were developed by Keim [34].

Water glass has a SiO_2/M^+-ratio of 4 : 1 (M = Na, K). In aqueous solution the silicate anion is polymerized into three-dimensional, nearly spherical particles which consist of ca. 90 SiO_2 units linked by oxygen bridges [35]. In its interior, the particles are free of OH groups and have a structure similar to that of β-cristoballite. On the surface, each Si atom is bound to an OH group. At pH 12, ca. 40 % of the OH groups are ionized to O^- groups. The potassium or sodium ions are hydrated by water molecules.

The reaction of water glass to form amorphous silica is mostly explained by the reaction with atmospheric CO_2 according to the equation:

$$K_2SiO_3 + CO_2 + n\,H_2O \rightarrow SiO_2 \cdot n\,H_2O + K_2CO_3$$

The reaction, however, is very slow due to the small amount of CO_2 in the air. Therefore, another process is mainly effective. The silica gel is very quickly formed in contact with porous materials when the water soaks into the capillaries and is withdrawn from the solution. Consequently, the solution is increasingly concentrated until the negatively charged colloidal silica particles come into such close contact to each other that the OH groups at their surfaces condense and macroparticles are formed, which then precipitate from solution [35].

This also explains why water glass is not appropriate for consolidating natural stones. Because the silica component is retained at the surface, only water penetrates deeper into the stone. The strongly consolidated surface zone rarely exceeds 1 or 2 mm. It is at risk of spalling off because it is underlain by an unconsolidated soft stone layer. Another reason for excluding water glass from conservation is the high content of alkali metals, which contaminate the treated material with hygroscopic alkali metal carbonates that can cause severe salt damage.

Silica sols gained importance in conservation only recently, but their application is described here because their chemical constitution is very similar to those of water glasses. Silica sols are solutions of colloidal silica (→ Silica, Chap. 4.). The particle size (7 – 125 nm) is greater than that of the silica particles in water glass solutions (2 – 3 nm). The particle size depends on the amount of dissolved silica, which ranges from 15 to 50 wt %. Silica sol solutions are slightly cloudy or milky depending on the size of the particles. The main advantage of using silica sols is

the greatly diminished content of alkali metal ions, mostly sodium, which reaches 0.5 wt % at most. Silica sols are produced from Na silicate solutions by reducing the sodium content by ion exchange with H^+ ions.

As in the case of water glass, the precipitation of the silica gel is caused by the loss of water, so that the hydroxyl groups condense and larger particles are formed. Although the particle size of some formulations of silica sols is very small, the product is not appropriate for consolidating porous materials because the silica particles are retained on the surface, where they tend to form an impermeable layer. The main field of application is the production of stone-repair mortars for filling smaller cracks or reshaping missing edges of square stones (Fig. 3). Thin silica-sol-bound washes are also used to protect surfaces with a sacrificial layer. Because of the low alkali metal content, the treated stones are not contaminated with salt and the risk of efflorescence is negligible. Detailed recipes for producing silica-sol-bound repair materials are described in [36].

3. Organosilicon Compounds

3.1. Strengtheners

During the weathering process, the loss of binding material leads to a decrease of strength in the outermost zone of sandstones and other building stones. The idea of structural strengthening is to replace the lost binding material by introducing an artificial binder into the space between the disintegrated and loose mineral grains. This can be achieved by applying reactive liquids which are taken up by the capillarities of the material and subsequently deposited a solid polymer or gel that fixes the loosened grains together. The aim should be a homogeneous depth profile of strength, as in the fresh unweathered stone.

Several polymers and gel-forming liquids are able to enhance the strength of a deteriorated stone. Due to its chemical similarity, a silicate-like system should be favored. The disadvantages of water glass are discussed in Section 2.5. Therefore the use of silicon organic compounds seems promising, since the gels formed from them are free of other compounds which might reduce the durability of the measure.

3.1.1. Tetraethyl Orthosilicate

Ethyl silicate has been widely used as stone strengthener since the late 1960s [37]. It is prepared from silicon tetrachloride by solvolysis with ethanol/water mixtures [38]. Depending on the amount of water added, a part of the resulting tetraethyl orthosilicate (TEOS) forms larger units by condensation. Monomeric or oligomeric TEOS is hydrolyzed by water present in the pore space of stones. Two hydrolyzed silanol (Si–OH) groups can condense by intermolecular release of a water molecule, thus forming stable siloxane (Si–O–Si) bonds. The final result is a solid gel structure which interacts with the mineral components of the stone (e.g., quartz, feldspars, rock fragments), whereby in many cases a stable contact results (Fig. 4).

Methyl silicate (tetramethyl orthosilicate TMOS), which reacts much faster than TEOS and was therefore frequently used in the 1960s and 1970s, is no longer used because it releases toxic methanol on hydrolysis.

The liquid TEOS products are applied either free of solvent or in ketone or alcohol solvents. Under the action of water in the pore space of

Figure 4. Formation of TEOS from $SiCl_4$. Gel formation by hydrolysis and subsequent condensation.

stones, a macromolecular gel is formed by hydrolysis, alkaline cleavage of a proton (Eq. 1) and subsequent condensation (Eq. 2). The overall reaction is catalyzed either by acids or bases, in the latter case yielding more branched rigid gels, while linear segments form in the presence of acids [39].

$$(RO)_3SiOH + OH^- \longrightarrow (RO)_3SiO^- + H_2O \quad (1)$$

$$(RO)_3SiO^- + (RO)_3SiOH \longrightarrow (RO)_3Si\text{–}O\text{–}Si(OR)_3 \quad (2)$$

In presence of bases, condensation is the rate-determining step. Step (1) becomes faster with increasing acidity of the proton. Since larger oligomers containing many Si–O–Si siloxane bridges are weaker bases than smaller units, their protons react more slowly. For this reason, the oligomers preferentially react according to Eq. (1), finally yielding highly branched molecules.

In the presence of acid catalysts the condensation of hydrolyzed species is faster than the hydrolysis itself, which then becomes the rate-determining step. In this case, hydrolysis is initiated by the electrophilic attack of a proton on an oxygen atom of the alkoxyl group (Eq. 3):

$$(RO)_3Si\text{–}O\text{–}R + H^+ \longrightarrow (RO)_3Si^+ + R\text{–}OH \quad (3)$$

This reaction does not depend on electronic but on steric effects: end groups are hydrolyzed faster than alkoxyl groups in the middle of a siloxane chain. Therefore, long linear chains are formed under acidic conditions.

Commercial products for stone consolidation are usually catalyzed by organotin compounds (e.g., dibutyltin dilaurate) or amines, which give a slower gel-forming rate and thus allow deeper penetration. The TEOS product most frequently used is Stone Strengthener OH or Conservare OH, a mixture of three parts of monomeric and oligomeric TEOS units dissolved in one part of solvent (mainly methylethyl ketone).

Depending on the reaction rate, which is influenced by temperature, humidity, and catalyst, different gel structures may form [40], [41]. In the course of hydrolysis and condensation which are competing steps, a network of connected ring structures $(\text{–O–Si–O–Si})_n$ is formed. Macroscopically, the gel consists of spherical particles several nanometers in diameter, which are piled together in an open structure with cavities between them. The rigidity of the three-dimensional structure prevents the condensation of all remaining silanol groups because the distance to neighboring silanol groups is too far for forming a siloxane bond. Moreover, at room temperature, the cavities the network are filled with water, ethanol, and TEOS molecules [42]. For steric reasons, the reaction will never lead to a stoichiometric SiO_2 network. The maturing process in the gel structure continues for several years and is accompanied by a continuous loss of water, which may lead to shrinking gaps in the structure as the aging of the gel proceeds (Figure 5).

Figure 6. Bars: Depth profiles of the flexural strength β of a weathered sandstone core (light grey) and a core treated with Stone Strengthener OH (dark grey). Lines: corresponding depth profiles of the elastic modulus E, determined from the slopes of the stress – strain curves. Greensandstone, Alte Pinakothek, München.

Thermogravimetric/differential thermal analysis (TG/DTA) measurements to monitor the mass loss during gel aging have been carried out [40], [43]. Detailed microscopic investigations on the interface between mineral surfaces and SiO_2 gel in the pore space of stones are given in [44].

The mechanism of fixing of the gel to the mineral substrate are not yet fully understood. The surface of quartz grains bears silanol groups which may well act as anchor groups for the gel. Thus, covalent siloxane (Si–O–Si) bonds can be formed by condensation at the interface. Hydrogen bonding between silanol groups of the gel and those of the substrate may also lead to a sufficiently strong but reversible adhesion.

3.1.2. Flexible Gels

Since a few years, modified TEOS products forming flexible gels have been commercially available. Gels formed from these products do not form shrinking gaps during the aging process. Flexibility of TEOS can be achieved by integrating linear soft segments into the rigid network of silica gels [45]. In this way, thin elastic and flexible films are obtained which cover the surface of macropores, binding together the mineral components. Compared with normal gels, the durability of the modified gels should be improved. The resulting gels can be water-repellent or hydrophilic, depending on the type of soft segment.

Linear segments of poly dimethylsiloxane can be integrated into the growing gel structure, and function like "expanders" that impart the desired elasticity to the gel. Due to the methyl groups in the bridging segment, these gels show water-repellent properties. Hydrophilic gels with elastic properties can be obtained by using polyether groups as bridging segments.

3.1.3. Coupling Agents

In most cases, sandstones show a marked increase in strength when treated with TEOS products. However, there are still major problems concerning the consolidation of limestones. The reason for failure seems to be an insufficient binding of the gel to the carbonate surface [46]. Moreover, the condensation reaction is retarded in the presence of calcite but not in the presence of quartz [47].

The effectiveness of TEOS in the consolidation of limestones can be improved by using adhesive coupling agents as additives [48]. Phosphate compounds can covalently link to the growing gel structure during the condensation reaction. The negatively charged phosphate groups are oriented towards the mineral surface, since calcite has a positive zeta potential in the normal pH region. Due to electrostatic interaction, the gel is tightly fixed to the mineral components. In contrast to the use of Stone Strengthener OH, a phosphate-modified TEOS product leads to a sufficient increase in strength when applied to Savonnière limestone.

In general, trialkoxysilanes with functional groups of different polarity (depending on the type of substrate) are useful coupling agents since they are covalently integrated into the gel network structure. The integration of aminopropyl trialkoxy silane (APS) into the gel network results in improved bonding to quartz and mica surfaces [48]. The interaction of the silanol groups of APS with glass surfaces is described in [49].

3.1.4. Effect on Stone Properties

Figure 6 shows an example for the depth profile of strength, determined on drill-core slices of a greensandstone core treated with Stone Strengthener OH compared to a drill core of untreated, weathered stone. The modulus of elasticity is enhanced simultaneously with the increase of strength, while it decreases with the structural disintegration caused by weathering.

Figure 7. Stress – strain curves of the biaxial flexural strength of Schilfsandstone slices. The slices were treated with different concentrations of a TEOS product. Front: untreated. The slope of the curves in the linear region (Hook region) is proportional to the E Modulus.

Investigations clearly demonstrate a non linear correlation between the amount of gel deposition and the modulus of elasticity E (Fig. 7) [50]. Low gel deposition values only lead to a negligible increase in E. However, if the gel deposition exceeds a certain value, a sharp increase in E is observed. Thus, in case of a high gel deposition, the stress – strain behavior of the outermost, treated zone may be completely different from that of the untreated interior. Especially when the penetration depth is low, shearing forces between the treated and the untreated zones are generated when the external humidity or temperature changes. It is often argued that the shearing forces may lead to subsequent delamination of surface scales.

As expected, the increase in the modulus of elasticity is diminished when flexible gels are deposited in the pore space of sandstones. Figure 8 shows a correlation between the E-modulus and biaxial flexural strength β, determined on Schilfsandstone slices treated with commercial Stone Strengthener OH and modified TEOS product in comparison with the untreated material. The increase in flexural strength is comparable in both cases, but the E modulus is lower for treatment with the modified product.

Figure 8. Correlation between E modulus and biaxial flexural strength β for untreated and consolidated stone (yellow schilfsandstone from Maulbronn).

As shown above, silica gels formed from ethyl silicate tend to form shrinking fissures due to continuous loss of structural water. However, laboratory and field studies [40] on numerous treated sandstones clearly show that there is no loss in efficiency even after 25 years. However, in the presence of hygroscopic salts, the durability may be greatly diminished due to mechanical stresses exerted by dissolution and recrystallization processes [51], [52].

TEOS products can be also used as binders for other restoration materials such as repair mortars, refilling grouts, washes, and varnishes [36], [53]. Compared with lime mortars, which are often used as sacrificial layers, TEOS products have the advantage of better durability against rain and acidic air pollutants. A further advantage is that full compatibility is guaranteed

when all restoration materials are based on the same chemical system.

3.2. Hydrophobic Products

The purpose of a hydrophobic treatment is to reduce the amount of capillary water taken up by a porous material. Since water participates in most damage processes (e.g., dissolution of calcite, ingress of reactive acidic air pollutants, swelling, frost), hydrophobization seems a useful concept for diminishing the weathering rate of stones. In ideal case, a water drop does not spread on a treated surface but remains in a sphere-like shape with a contact angle of $> 120°$ for several hours until it evaporates (Fig. 9).

Figure 9. Sperical water drop on a treated sandstone surface (right) in comparison to an untreated sandstone, where the drop spreads and moistens the surface (left)

3.2.1. Formulations

Nearly all water-repellent agents used for the hydrophobic treatment of stone form silicone resin films as a final product. The precursors may be monomers like alkyltrialkoxysilanes or oligomeric/polymeric siloxanes. These compounds are frequently applied in aromatic hydrocarbon (rather than ethanolic) solutions of various concentrations. Similar to TEOS, after hydrolysis and condensation the precursors are linked together by siloxane bonds, finally forming a polymeric silicone resin (polysiloxane). Solutions of silicone resins can also be used. After evaporation of the solvent, the resin remains in the structure as a water-repellent film.

The basic compounds for the production of alkyltrialkoxysilanes as well as their oligomeric and polymeric homologues are trichloroalkylsilanes. The monomeric alkyltrialkoxysilanes are formed by addition of alcohol, while alcohol/water mixtures result in the formation of oligomeric siloxanes. A larger amount of water leads to a longer chain. Polymeric silicon resins are obtained by reaction with pure water (Fig. 10).

In contrast to alkylsilanes/siloxanes, the siliconates formed by addition of alkali metal hydroxides (Fig. 10) are water-soluble due to their ionic properties. This may be advantageous in some applications. However, since soluble carbonates are formed as undesired byproducts, the use of these products for hydrophobic treatment of building facades has decreased. Siliconates, however, are still often applied as injection liquids against rising damp.

Unlike the gel formation of TEOS, where each silicon atom has four oxygen neighbors, in alkylsilanes/siloxanes one binding position is blocked by the alkyl group. Thus, sheetlike structures are formed during condensation.

As in the case of TEOS gels, the binding mechanisms of the polysiloxane films to the mineral surface are not fully understood. Since hydrolysis and condensation are competing steps, a growing siloxane still has silanol groups which may interact with OH groups on the mineral surface. The binding interaction may be achieved by hydrogen bonding or by subsequent covalent bonding after release of water (Fig. 11).

In the ideal case, the alkyl groups ("umbrellas") should be oriented outwards thus giving an optimized water-repellency to the coated surface (Fig. 11). However, due to the different interatomic distances of silanol and other OH groups on the surface of minerals, which are different from those of the silanol groups in the forming siloxane, it is most improbable that sheath structures can develop on the surface. In addition, the formation of sheets is prevented by steric

Figure 10. Production of different silicon organic hydrophobic agents from trichloroalkylsilane. Reaction steps required to form a silicone resin film in the pore space of stones [54].

effects of the bulky alkyl groups. Therefore, silicon resin films more likely consist of tangled R–SiO_3 chains [46].

Since the concentration of silanol groups on the surface of quartz is rather high, sandstones with a high quartz content show good hydrophobic properties when treated with silanes/siloxanes. The films are tightly connected to the mineral surface. Similar results are obtained when the surface of a stone has been previously coated with gel by a TEOS strengthening treatment. This seems reasonable, since silica gel has a high concentration of free silanol groups. In contrast, clay minerals offer silanol groups to which siloxanes can link only along their edges, so that polysiloxane films are suspended like sails from edge to edge of different clay particles (Fig. 12). Since the density of silanol groups on the basal planes of clay minerals is negligible, the interaction is much weaker in these areas. Probably, van der Waals interactions are exclusively responsible for the contact between clay basal planes and polysiloxane films. Therefore, water molecules can displace the silicone resin film in the persistent presence of water. In the case of calcite, it is likely that the weak Ca–O–Si bonds which link the calcite surface to the polysiloxane film can be easily hydrolyzed and broken up by protons.

Figure 11. Reaction and bonding mechanisms of alkyltrialkoxysilanes [55].

Figure 12. Holey, house-of-cards-like chlorite structure in a clay-rich sandstone, spanned over by a silicone resin film by a treatment with a polysiloxane (W 090 S). Breitbrunn sandstone. SEM image: 44 × 44 µm [46].

The water-repellent properties of a silicone resin are determined by the length and degree of branching of the alkyl groups. While products with long alkyl chains show better water-repellency, their ability to penetrate into narrow pores is reduced. While this effect is of major importance in the case of concrete, most sandstones show a sufficient penetration of products with long alkyl chains since their capillary pores are in the range of 10 to 100 µm, which exceeds the diameter of a bulky alkyl group by a factor of around 100 to 1000.

Under basic conditions (concrete, fresh mortar), the Si–C bond can be cleaved easily when the alkyl chain is short, and methylsilicone resin is not stable under these conditions. Hydrophobing agents showing stability towards alkaline attack consist of isobutyl or isooctylsilanes/siloxanes.

3.2.2. Combined Products

Since the early 1970s, combined products have been available consisting of mixtures of TEOS (strengthener) and oligomeric siloxanes (hydrophobing component). The main advantage is that both strengthening and hydrophobing can be carried out in one step, which makes the planning of restoration measures easier and reduces the cost. Moreover, the interaction of the gel surface with the silicone film is optimized when both macromolecules grow at the same time (cross-condensation). The most prominent of such conservation products is Wacker H, a mixture of TEOS and oligomeric siloxanes with different alkyl groups such as methyl, butyl, and isooctyl.

3.2.3. Microemulsions

Since 1990, aqueous hydrophobic agents are available as microemulsions which have the main advantage of being free of toxic solvents [56]. They contain droplets of a silane/siloxane dispersed phase stabilized by two types of surfactants. Since the surfactants also consist of silanes/siloxanes, the system only contains the reactants necessary to form the desired polysiloxane film inside the pore space.

In normal oil/water-type emulsions, the disperse phase is covered by a single surfactant

Figure 13. Depth profile of water absorption, determined on slices from a treated and an untreated sandstone core by weighing after 24 h of immersion in water. Bunter sandstone from Fritzlar Cathedral, treated with W 290 S (oligomeric siloxane) after strengthening with Stone Strengthener OH.

that forms a molecular layer with quasicrystalline properties ("solid condensed film"). Due to strong cohesion forces within the disperse phase, these well-ordered structures are rigid and exhibit only little tendency to form curved surfaces. Thus, the colloidal spherical particles have a rather large diameter of about 1000 nm, and these emulsions are not capable of entering the narrow capillaries of the stone structure.

Using an additional second type of surfactant (cosurfactant) with a shorter nonpolar alkyl group disturbs the ordering of the monomolecular surfactant layer. As a consequence, the cohesion forces of the disperse phase exceed the attractive forces between the two surfactant phases, so that the tendency of the disperse phase to form a curved surface is greatly enhanced. The diameter of the resulting colloidal spheres lies in the range of 10 – 80 nm, which is small enough to penetrate the narrow pore space of stones.

Frequently, ammonium acetate functionalized polysiloxanes are used as surfactants. During the drying process in the stone, small amounts of acetic acid are formed which act as a catalyst for the condensation reaction. Moreover, these functional groups can act as adhesive coupling groups to the substrate. The shorter chained cosurfactants normally consist of silanes or oligomeric siloxanes. The disperse phase is a mixture of silanes, siloxanes, and polysiloxanes.

Since microemulsions consist of reactive components that eventually form silicon resins, they do not exhibit long-term stability. However, when microemulsions are prepared with only small amounts of water, the concentration of micellar aggregates which can form ordered spatial structures is increased. Within these so-called mesophases, the water can be regarded as being dissolved in the surfactant phase. Mesophases show a markedly higher stability. Therefore, microemulsions are only sold as concentrates which are diluted with water before application. Normally, dilutions of 5 to 15 % concentrate in water are used for a water-repellent treatment of stone. Once water is added, the product should be used within 24 h.

3.2.4. Effect of Hydrophobation on Stone Properties

The range of the capillary water absorption coefficient of sandstone is on the order of $0.8\,\mathrm{kg\,m^{-2}\,h^{-0.5}}$ up to more than $20\,\mathrm{kg\,m^{-2}\,h^{-0.5}}$. After water-repellent treatment, the value decreases to $< 0.1\,\mathrm{kg\,m^{-2}\,h^{-0.5}}$, regardless of the initial value. This is equivalent to a water absorption of less than $100\,\mathrm{mL/m^2}$ during one hour of driving rain, which is a very low value.

The effect of hydrophobicity can be determined as a function of depth by storing slices cut from a drill core from a treated facade under water for 24 h (Fig. 13). To avoid sharp gradients between treated zone (dry) and the untreated material behind (moistened), a smooth increase of water absorption towards the interior should be aimed for. Whether this aim can be achieved depends on the penetration depth of the silane/siloxane solution, which in turn is influenced by the capillary absorbency of the stone.

Therefore, stones with capillary water uptake coefficient lower than $1.0\,\mathrm{kg\,m^{-2}\,h^{-0,5}}$ need no treatment with water-repellent agents because their water capacity is already sufficiently low. On the other hand, in case of a dense stone a penetration depth of the hydrophobic agent of a few millimeters has the same effect as one of several centimeters in the case of a very porous stone.

The aims of a hydrophobing treatment are:

- To prevent wet absorption of reactive gases such as sulfur dioxide and nitrous oxides
- To prevent migration and subsequent enrichment of soluble salts
- To reduce damage from hygroscopic swelling and frost
- To stop biological growth
- To diminish the amount of dust fixation and to prevent the formation of crusts.

However, in many cases, an impregnation is carried out only for esthetic reasons, i.e., to prevent re-soiling of a freshly cleaned or new facade, regardless of the absorbency and the mineralogical composition of the stone.

Laboratory investigations of hygroscopic swelling and shrinking of siloxane-treated and untreated clay-rich sandstone yielded surprising results [57]: drill-core samples of Abstwinder Schilfsandstone, fixed in a dilatometer, were stepwise wetted by rising the atmospheric humidity at 20 °C and finally stored under water for 48 h. After each step, the hygroscopic dilation and the moisture content were measured by weighing. Figure 14 shows the hygroscopic dilation of alkylsilane-treated and untreated material. The amount of water absorbed is reduced by the impregnation to some 40 % of the value for untreated stone. However, the corresponding hygroscopic dilation is enhanced for a given moisture content. In spite of a strongly reduced water uptake, the hygroscopic dilation for complete wetting is only reduced by 20 %. Under varying atmospheric humidity, treated samples react with a higher amplitude of dilation than untreated ones. A possible explanation is the following:

In the untreated material, hygroscopic dilation processes of clay minerals are transmitted into the structure to a certain extent, which depends on the pore size and geometry of the particular grains and clay matrix. If resin films are deposited in the pore space, transmission to the structure is enhanced, and the deposited material acts like a wedge and causes greater hygroscopic swelling. Since the frequency of humidity changes is much higher than that of rain fall, the risk of subsequent damage to clay-rich sandstones and limestones could be greatly enhanced.

The example shows clearly that the priority is not to exclude capillary water from the pore space but to reduce the damaging effects of water. However, a similar effect of increased hygroscopic swelling has not been measured for all organosilicon hydrophobizing products. Moreover, the same product did not behave similarly on different kinds of stone. Therefore this effect cannot be generalized, but it is recommended to test in each case whether hydrophobic treatment enhances hygroscopic swelling.

Figure 14. Hygroscopic dilation as a function of moisture absorption, determined after storing treated and untreated samples in air of different humidity and subsequent storing under liquid water to equilibrium
Full line: siloxane-treated clay-rich Schilfsandstone (Abtswind); Dotted line: untreated reference material [57].

3.2.5. Durability

Research has clearly shown that water repellents based on silicone resins show a pronounced drop in efficiency after a period of some years. Especially in the surface region, they are able to prevent the capillary uptake of water only for a short period of time [58].

The effect of UV radiation on the decrease in water repellency of silicon resins does not play an important role in practice. Investigations on formerly treated sandstone facades of the Alte Pinakothek in Munich having different exposure directions did not show any notable difference

between south and north walls; the rate of decrease was approximately of the same order.

Observations on treated buildings [59] and laboratory results [60] suggest that the main reason for the reduction in efficiency is the deposition of hydrophilic dust particles in the outermost grain layers. Thus, a thin surface layer is formed which is able to take up water again. This zone is sharply separated from the intact water-repellent zone inside. The decrease in water repellency proceeds from the surface towards the interior. In most cases, the thickness of the hydrophilic surface zone is less than 1 mm, while the interior parts still show strong water repellency. Therefore, because rain or dew does not soak into the interior of the material, the surface is more strongly exposed to strong wetting and drying than in the absence of hydrophobic treatment. In addition, the following observations have been made:

1) Expecially on limestones, the enhanced wetness burden of the surface leads to intensive biological growth. Additionally, in contrast to non carbonate sandstones, the pH range of limestones (7 – 8) also favors the growth of microorganisms. However, there is no evidence that silicone resins themselves might serve as a food resource for microorganisms.
2) Cleaned and impregnated limestone facades may look clean only for a period of some three to five years, after which a brownish or grayish crust begins to form. In some cases, the fixation of dust seems to be even more intensive than on untreated facades. A comprehensive explanation for this observation is still missing. However, it seems likely that the resoiling of facades is enhanced by persistent water films that spread within the thin hydrophilic surface layer in front of the intact hydrophobic zone in the interior.
3) Isolated water drops which run down from moldings or other protruding parts of ornaments leave ugly black tracks because they do not soak into the pores of the stone.

Salts strongly diminish the durability of hydrophobic treatments because water vapor can still diffuse into the pores. Hygroscopic salts which are imbedded in a polysiloxane network are therefore still able to dissolve and recrystallize under conditions of varying relative humidity thus destroying the polysiloxane and reducing the effectiveness.

4. Acrylates

Acrylates are very important in the conservation of building materials. The most important acrylic monomers are listed in Table 1 [61].

Polymerization at or near room temperature, as required for building conservation, can be accomplished by free radical initiation with reaction initiator pairs, among which dibenzoyl peroxide (DBP), dimethylaniline (DMA), and dibenzoyl peroxide DBP dimethyl-*p*-toluidine (DMPT) are widely used. At room temperature, the mixture of DMA or DMPT with DBP produces free radicals at a conveniently rapid rate to transform the acrylic monomers into the corresponding polymer resins, whereas DBP alone causes polymerization at a reasonable rate only above 60 °C.

Mixtures of two or more acrylic compounds may be used to produce copolymers and terpolymers having properties different from those of the homopolymers. The properties of the final products are mainly influenced by the initial ratio of the starting materials and the polymerization conditions. The glass-transition temperature T_g largely determines the suitability of a acrylic polymer for conservation purposes. At 10 °C below T_g the polymer is hard and glassy, and 10 °C above, it is flexible. The T_g of an acrylate should be below or above the temperature range to which the treated object is exposed so that no variations in mechanical properties of the polymer take place.

In contrast to several other polymers, acrylates show no or only very little yellowing. Moreover, yellowing is not caused by the acrylate compound itself but by the hardener, of which amine hardeners are most prone to change their color. For this reason, if the appropriate hardener is used, acrylates will remain without discoloration even for decades. For conservation of building materials reactive acrylate and polymer acrylate systems are used.

4.1. Reactive Acrylate Systems

Reactive systems are based on monomer or oligomeric prepolymer acrylates which are

Table 1. General formula of principal acrylic monomers $H_2C{=}CXY$ and as polymer units $(–H_2C–CXY–)_n$

Structural Unit	Abbreviation	X	Y	T_g of Polymer, °C
Methyl methacrylate	MMA	CH_3	$–C(=O)O–CH_3$	ca. 100
Ethyl methacrylate	EMA	CH_3	$–C(=O)O–CH_2–CH_3$	65
n-Propyl methacrylate	nPMA	CH_3	$–C(=O)O–CH_2–CH_2–CH_3$	35
Methyl acrylate	MA	H	$–C(=O)O–CH_3$	10
Ethyl acrylate	EA	H	$–C(=O)O–CH_2–CH_3$	− 24
Acrylic acid	AA	H	$–C(=O)OH$	

polymerized within the material to be consolidated. Polymerization is catalyzed by redox pairs which are effective at room temperature. Oxidizing compounds include peroxides, chlorates, bromates, hypochlorites; reducing agents are sulfites, hyposulfites, thiosulfates, amines, mercaptans, and others [62].

In contrast to polymeric systems, reactive acrylates were never in wide spread use because in practice there are problems with adapting them to the various conservation problems. Their main application is the filling of small cracks in tiles, paving slabs, and dense limestones such as red nodulus limestones. However, because the course of polymerization is dependent on the amount of acrylate to be polymerized, the dosage of the catalyst is very difficult to adjust. If the amount of arylate to be polymerized is big, the amount of catalyst is small, and vice versa. Therefore, if for a given volume of acrylate the content of catalyst is too high, the system starts to boil and bubbles are formed which then spread over the surface. If the amount of catalyst is too low, the system reacts very slowly or polymerization even ceases, so that the solution will not solidify. In practice the problem of finding the right catalyst content arises because the width and depth of cracks and therefore the volume of acrylate varies. Furthermore, reactive acrylate systems are sensitive to moisture and oxygen, which inhibit polymerization. Because these can not be excluded during practical work, the reactivity can not be controlled with the necessary accuracy.

Moreover, all reactive systems show a large shrinkage (10 – 15 vol %) during polymerization, so that the acrylate polymer tends to detach from the crack flanks. Consequently, the gluing effect diminishes, and the secondary pores which are formed allow the further penetration of water and acidic pollutants. To avoid such drawbacks several reactive acrylates contain a small amount of acrylic acid, which acts as a surfactant and can be incorporated into the polymer network. Acrylic acid is mainly effective for limestones and mortars because the acid can affect the calcite surface and form calcium acrylate.

In the Aachen Concept of stone conservation [63–65] efforts were made to develop acrylic prepolymers alone or in combination with epoxides that do not exhibit the above mentioned disadvantages [66–68]. However, in spite of promising laboratory test results [65], [67], [69], products have not yet appeared on the market.

4.2. Polymer Acrylate Systems

Polymer acrylates are used in the conservation of stones, brick, terracotta, tiles, porcelain, wall paintings, renderings, metals such as copper, bronze and brass, and in some cases even textiles. Hardly an area of conservation can be found where acrylates have not been used to repair or stabilize fragile objects.

The best known product is Paraloid B 72 from Rohm & Haas, a ethyl methacrylate-methyl acrylate copolymer. Many similar products with different glass-transition temperatures and mechanical properties are in use. Another widely used product is Motema Finish X from Interacryl, a butyl methacrylate – methyl methacrylate copolymer which has a lower T_g (65 °C) and a lower modulus of elasticity than poly(methyl methacrylate) ($T_g = 100$ °C) [70].

Polymer acrylates are mainly applied as 2 – 10 % solutions in organic solvents such as acetone, butyl acetate, and toluene. The volatility of the solvent decisively determines the area and method of application. If greater penetration into pores or cracks is required the solvent should evaporate slowly. The effectiveness is based on the formation of a thin polyacrylate film which covers the surfaces of the treated

materials. However, polyacrylates cannot deeply penetrate into narrow-pore materials; they are retained at the surface or within the first few millimeters and tend to form a thin surface coating which is at risk of spalling off if the modulus of elasticity of the impregnated surface layer is much higher than that of the underlying material (stone, brick, rendering). As a consequence, polyacrylates are mainly used for the conservation of limestones or marbles. Especially in Italy, many objects have been treated during the past 25 years [71]. Polyacrylates can be recommended if the decayed layer that has to be consolidated is only of a few millimeter thickness and if the underlying material is unweathered and of good strength. If, however, penetration of more than a few millimeters is required, as in the case of many weathered sandstones, application of polyacrylates is dangerous because the treated surface layer is at risk of spalling off within a short time.

Several attempts have been made to combine the consolidating effect of acrylates with a hydrophobic effect. Besides the numerous private recipes that circulate among restorers, two formulations using solutions of DRI FILM (prepolymer of methyltrimethoxysilane, MTMOS, General Electric) and Paraloid B 72 became popular [72], [73]. The product is also best known under the name Bologna Cocktail. However, in each case it must be decided whether a hydrophobic effect is desired or not.

4.3. Total Impregnation with PMMA

For the time being, the technical process of total impregnation with PMMA is only be carried out by Imchemie Stone Conservation which is based in Schesslitz near Bamberg, Bavaria. The objects must be transported to the firm because the impregnation can only be executed in a special vacuum – pressure chamber.

Before the process itself, the object is dried in an oven at 60°C for several days or even weeks depending on its size. A description of the whole process can be found in [74], [75]. After cooling to room temperature, the object is placed in the vacuum-pressure chamber. The volume of the chamber is such that objects up to a size of $4 \times 2.5 \times 2$ m can be treated. The chamber is then evacuated for several days until technical vacuum is reached and the pores are emptied of air. Then the monomer, a mixture of methyl methacrylate (MMA) and a small amount of butyl methacrylate, is let into the chamber until the object is totally immersed. The MMA fills all pores and penetrates to the very core of the stone. Then the chamber is flooded with nitrogen and the pressure is raised to 10 bar, so that excess MMA is pumped back into the reservoir. The polymerization is started by raising the temperature.

The process of polymerization is controlled by a variety of peroxides which decompose at certain temperatures (the exact composition of the peroxides is a trade secret). The polymerization is a strongly exothermic process which under normal conditions would lead to boiling of the liquid. Therefore, the treatment is carried out under pressure so that the formation of gas bubbles is suppressed.

Figure 15. Ansbacher Schilfsandstone, treated with the Ibach Method. The PMMA completely fills the entire pore space. Isolated shrinkage bubbles can be observed within the PMMA.

At the end of the polymerization process, the temperature has reached ca. 70 °C. Polymerization normally takes one week or even longer. When polymerization is complete, the object is allowed to cool slowly to room temperature over several days. After returning to normal pressure, the object can be removed from the chamber. The whole pore space is filled with solid PMMA, and the formerly porous material no longer absorbs water. Figure 15 shows a SEM

image which demonstrates the complete pore filling with PMMA in the case of a treated sandstone. Within the PMMA, isolated vacuoles can be recognized whose formation is caused by shrinkage in the course of polymerization. The shrinkage bubbles only occur within the PMMA and not at the interface between PMMA and pore wall, because the coupling agents which are added to the impregnation solution prevent the detachment of the PMMA from the pore walls. Even experts are unable to distinguish treated objects from untreated ones by mere visual inspection because their appearance remains unchanged.

Since 1978 total impregnation with PMMA has been frequently applied in Bavaria for sandstone objects, such as tombstones, balusters, garden benches, and sculptures. By general agreement among restorers and public conservation authorities, important works of art are still excluded from treatment with the Ibach method because it is irreversible. Only objects whose condition is so poor that conservation with conservative means will not provide the necessary durability are treated.

The Ibach method has now been applied to marble in the case of the niche and gable figures of the Glytothek in Munich. Several investigations were carried out to transfer the process from sandstone to marble consolidation, because appropriate coupling agents had to be found. Coupling agents control the shrinkage of 19 vol % which occurs during the polymerization process. The coupling agents ensure that the shrinkage bubbles do not occur between the mineral surface and the PMMA, but only as isolated vacuoles within the PMMA itself if the correct concentration of coupling agents is added [76]. Only after a sample treatment with a figure of 1 m in size had yielded a perfect penetration, was the first monumental figure of Peter Vischer from the Glytothek subjected to total impregnation in 1983.

5. Epoxy Resins

Epoxy resins are two-component plastics which consist of the epoxy resin itself and a hardener (→ Epoxy Resins). Bisphenol A resins are widely used in industry and building conservation.

Bisphenol A reacts with epichlorohydrin in two steps to form Bisphenol A diglycidyl ether.

Bisphenol A diglycidyl ether

The Bisphenol A diglycidyl ether molecules are condensed into linear long-chain molecules which constitute the Standard Bisphenol A epoxy resins (see bottom).

Cold-hardening epoxy resins, which are of interest for building-conservation purposes, are transformed into solid epoxy resin by means of tetrafunctional aliphatic amine hardeners. The addition of the amine to the epoxy group leads to β-hydroxyamine links between resin and hardener and the formation of a spatial network (Fig. 16).

To adapt epoxides to the requirements of stone conservation, several experiments have been conducted within the framework of the Aachen Concept of stone conservation [63], [64], [66], [67]. Among them, a modification of the epoxide system with an glycidylmethacrylate (GMA), a methacrylate with an epoxy side chain, yielded promising results, because the hardening rate as well as the mechanical properties of the resulting resin could be successfully influenced [68]. More detailed information about the possibilities of the molecular design

Standard Bisphenol-A epoxy resin

Figure 16. Epoxy resin formation with tetrafunctional amines

of epoxides can be found in [77–79]. The laboratory experiments were accompanied by SEM studies on impregnated stones in order to assess the quality of the polymer films within the pore space [80].

In building conservation, epoxy resins are used because of their high adhesive strength. Depending on the type of epoxy resin, an adhesive strength of up to 30 MPa or even more can be obtained. For this reason, the main field of application is the repair of broken pieces that must be glued together or the fixation of dowels or anchors.

Among scientists and restorers, contradicting opinions still exist about the suitability of epoxy resins for consolidating decayed stones. In particular in the former German Democratic Republic, several natural stone outdoor sculptures were consolidated with epoxy resins, which still seem effective after almost 20 years of exposure. However, because of the insufficient penetration depth of most epoxides, treatment was carried out by means of pressure injection, for which many holes had to be drilled to allow injection of the resin deep into the stone.

One of the major risks in the use of regular commercial epoxides for consolidation of decayed stones is the separation of the resin and the hardener due to chromatographic effects within the narrow pore space of the stone, whereby one of the components can be retained at the pore surfaces while the other component penetrates deeper [81]. As a consequence, the resin will not or only insufficiently harden without having

an consolidating effect. A further drawback of normal epoxides is their proneness to yellowing, which can cause ugly discolorations. Moreover, the modulus of elasticity of regular commercial epoxy resins, which were designed for other purposes, is too high, so that consolidated surface parts of stones are at risk of spalling off with time.

For this reason, consolidation of stone with epoxy resins is still in the research stage [63–65], [67], [79]. The selective adsorption of the resin or hardener can be prevented by preparing a quasi-one-component system by controlled linking the two reaction partners. Using a tetrafunctional hardener with a bifunctional resin (Fig. 16) yields highly linked macromolecules which result in high viscosity of the liquid. Sufficient penetration into a pore system is no longer possible. To produce defined quasi-one-component epoxy systems, the resin or the hardener must be chemically modified so that only two resin molecules are connected to one hardener molecule. This can, for instance, be achieved by replacing one of the epoxy groups with an activated Michael system, which is more reactive than the epoxy group [79].

Moreover, by inserting a further Bisphenol F unit into the resin molecular chain a lowering of the modulus of elasticity of the final product is achieved (see below).

The effect of epoxy resins on the mechanical properties of selected natural stones in comparison to other consolidants has been extensively investigated [82].

Epoxy resins are suitable for preparing stone-repair materials. Because the mixing ratio of aggregate and binder can be lowered to 1 : 15, the appearance of the resulting mortar is very similar to that of stone. The advantage of epoxy-bound repair mortars is that their color can be more easily adapted to a natural stonelike appearance than that of lime or cement-bound mortars because the epoxy resin is colorless and its proportion in the mixture is lower than in the case of inorganic binding materials. Mortars with a low binder to aggregate ratio show a high porosity; their capillarity, which is similar to that of natural stones, strength, and modulus of elasticity are moderate. However, repair mortars based on epoxy resins also exhibit the problem of yellowing under outdoor exposure, and this can lead to an ugly patchy appearance of treated facades.

Epoxy-based mortars with a higher resin content are very dense and can be polished. Therefore they can be used for repairing decorative stones like colored limestones, schists or marbles. In these cases the result is mostly much better than with lime- or cement-based mortars.

6. Polyurethanes

Isocyanates and polyalcohols are the starting components for producing polyurethane resins. The reaction product is a polyurethane chain

Activated Bisphenol A resin

Epoxy group Hydrogenated Bisphenol F Bisphenol A Reactive Michael system

Activated, flexible Bisphenol resin

which can further polymerized to a polyurethane network.

To adapt polyurethanes to the requirements of stone conservation, intensive research has been undertaken within the joint research program "Steinzerfall – Steinkonservierung" (German: stone decay/stone conservation), funded by the German Federal Ministry of Education and Research (BMBF). The research, which was largely focused on the development of modified polyurethanes became known as the Aachen Concept for stone conservation [63], [64], [66], [67]. Because monomer solutions exhibit several problems in case of stone conservation, prepolymers must be used which consist of hard and soft segments to lower the elasticity of the resulting film (Fig. 17).

In the first step, a segmented prepolymer is formed by the reaction of a diisocyanate and a diol. The elastic properties are mainly determined by the length and the chemical nature of the soft segment, which in most cases is located in the diol component. In the Aachen Concept [79], the segmented prepolymer consists of isophorone diisocyanate as the hard segment and a hydroxy-functionalized oligomethylsiloxane as the soft segment (silane-modified polyurethane).

Depending on the desired reactivity, the prepolymers can contain from 0.1 to almost 10 wt % of monomer. The prepolymers are dissolved in organic solvents, which also determine properties such as penetration and reactivity. The amount of polyurethane compound in the product is on the order of 30 wt %.

The segmented prepolymer is applied to the stone, and the reactive O=C=N – groups at both ends of the molecule react with the humidity within the pore space to form the final polyurethane film. A byproduct of the reaction is CO_2, which evaporates. Due to the methylsiloxane component, the film has hydrophobic properties.

By varying the length of the soft-segment chain, the mechanical properties of the polyurethane film can be deliberately controlled. For a given length of the hard segment, polymer films with a $C_3 - C_4$ soft segment are brittle, and those with $C_9 - C_{12}$ segments are fluid. Only those with C_5 or C_6 soft segments are flexible and appropriate for stone conservation.

The film formation of polyurethanes in the presence of different salts has been investigated [80], [83]. The reaction rate is lowered, and the films no longer cover all salt crystal surfaces completely, so that salts can be mobilized by moisture. For this reason, in the presence of salts the use of a catalyst such as dibutyltin dilaurate is necessary. The influence of Aachen-type polyurethanes on the mechanical and moisture-transport properties of impregnated stones was investigated [65], [82], and the effect of polyurethane treatment on the swelling and shrinking of natural stones under different moisture conditions measured [84]. Information about the durability of treatments in time-lapse laboratory tests can be obtained from [85].

7. Polyester and Alkyd Resins

Unsaturated polyesters (UP) resins consist of a multibasic, unsaturated carbon acid (phthalic acid, maleic acid, fumaric acid, etc.) and dihydric alcohol, such as ethylene glycol, propanediol, or butanediol (→ Polyester Resins, Unsaturated). The two components are dissolved in monomers which form bridges between the double bounds of the acid and the alcohol. These include styrene, methylstyrene, and methyl methacrylate. The reaction is catalyzed by peroxides, Co salts, or tertiary amines.

Alkyd resins (→ Alkyd Resins) basically consist of the same or similar unsaturated acids and alcohols, which are dissolved in reactive substances such as styrene, acrylates, or epoxides that can link the polyester chains into a three-dimensional network. Alkyd resins are modified with 15 – 75 % fatty acids or oils such as linseed oil, soybean oil, or castor oil.

In stone and building conservation, polyesters are mainly used as constituents in paints (alkyd paints) or as binders in stone-repair mortars. Especially in the 1960s and 1970s, many repairs on limestones and marbles were carried out with polyester-bound materials. However, polyester repair mortars did not prove as durable as expected because their thermal expansion is much greater than that of all mineral building materials, so that sooner or later the repair patches detached from the substrate. Moreover, the repair mortars become brittle and bleach out because of ongoing cross-linking of the chains

Figure 17. Reaction path for produce a polyurethane stone-conservation product

and oxidation of hydrocarbon molecules. Today, the majority of polyester repairs have already fallen out or are so loose that they can be removed very easily. In restoration and conservation, polyester repairs should be removed and replaced by mineral-based repair mortars.

Polyester repair mortars are still used for filling defects in pavement or facade slabs made of natural stone. Filling of the defects which occur in many stones is often necessary for polishing. If the polyester repairs are carried out appropriately they can hardly be recognized after polishing. However, the method can not be recommended for large facades where the slabs are exposed to strong light, wind, and rain because the repairs would detach in a quite short time. Polyesters are also very used for gluing steel anchors by which facade plates are fixed.

Between 1960 and 1970 in Germany, the polyester product Lemisan was used as consolidant for weathered sandstones and limestones. Lemisan was an unsaturated polyester dissolved in styrene and diluted to a concentration of 10 – 15 % with dichloromethane. The product was not a special development but corresponded to the product Leguval W 16 from Degussa, which was simply diluted to adapt its properties to the needs of stone conservation (capillary penetration into porous materials). Because Lemisan did not penetrate deeply enough into the stones, in several cases the detachment of scales parallel to the surface was observed whose thickness exactly reflects the penetrated and consolidated zone. An example is shown in Figure 18.

Figure 18. Thin desquamations on a polyester-treated sandstone facade. Parish church in Oberdachstätten near Ansbach, Bavaria.

8. Polymer Dispersions

In building conservations, several aqueous polymer dispersions are used to modify the properties of inorganic materials such as mortars or lime paints and to adapt them to special requirements. For instance, polymers like poly(vinyl acetate), acrylates, polyurethanes, and epoxides are also available in aqueous dispersion. However, this method of improving the workability of a well-known inorganic systems is not an invention of the 1990s. Already in antiquity, craftsmen used natural polymers such as casein, collagen, egg albumin, and blood albumin, whose ef-

Table 2. Properties of polymer dispersions which are most frequently used in building conservation

∗∗ Critical temperature of film formation.

fects on different mortars were intensively investigated [86]. Table 2 presents an overview over the most common modern polymer dispersions.

Because polymer dispersions can be diluted with water to any desired degree, their properties can vary over a very broad range. Moreover, polyurethane or acrylic dispersions, for instance, are large classes of chemical substances whose properties differ greatly, so that the figures presented in Table 2 is only a rough guide of the respective properties.

To synthesize polymer dispersion in an aqueous medium, special preparation techniques are necessary. Prepolymers are dispersed in water as small droplets and surrounded by an protective colloid. Specific catalysts within the prepolymer droplets then start the polymerization to form a solid polymer particle. The stability of the resulting emulsion is secured by the presence of protective colloids which surround the polymer particles, whose size is in the range of 0.1 to 5 µm. Because the size of the polymer particles is in the order of the wavelength of visible light, the emulsions are cloudy of milky white due to the scattering of light.

The major advantage of polymer dispersions is that they can be added to all classical building materials which are worked with water. When applied to a building material, the dispersion breaks in the course of evaporation of water, forming a polymer film which covers the surface of the mineralic substrate.

The main fields of application are as follows:

- Paints: dispersion lime or silicate paints for indoor or outdoor application
- Mortars: polymer aided mortars for various applications such as repair mortars, joint mortars, spatala materials, fixation of wall and floor tiles
- Renderings: polymer-aided renderings
- Concrete: polymer-aided concrete where particular requirements with respect to damp-proofness, acidic resistance, and solvent resistance exist
- Primers: primer layer of polymer dispersion to improve the adhesion of lime or hydraulic mortars to mineral building materials.

The effect on the mechanical properties of the mortars is significant. Whereas the modulus of elasticity is lowered in most cases, bending strength as well as compressive strength increase markedly. However, there is no linear increase in bending and compressive strength with increasing polymer content. The most striking influence is observed in case of adhesive strength (pull-off strength) which can reach values of 1 – 2 MPa or more. It increases almost linearly with increasing polymer content.

Modern stone-repair mortars based on polymer-aided cement as binder show a modulus of elasticity as low as that of lime mortar (4 – 6 kN/mm^2) and a strain that is about ten times higher than that of regular mineral mortars ($\varepsilon = 0.2 - 0.5$ mm/m). Tables 3 and 4 contain some illustrative data from [87], [88]. The results clearly demonstrate that the effect of polymer additives on different mortars cannot be simply predicted but have to be measured in each case.

However, the disadvantages of high polymer content in building materials must also be mentioned. The polymer film shows much greater

$*$ β_{BS}: bending strength, β_{CS}: compressive strength, β_{POS}: pull-off strength, w/c ratio: water/cement ratio. $**$ PVP: poly(vinyl propionate), PA: polyacrylate

hygroscopic swelling under changing moisture conditions than mineral building materials. For this reason, paints with a high content of dispersion very often peel off when the pull-off strength of the underlying rendering is insufficient. Likewise the water-vapor permeability decreases with increasing polymer content, a particularly problematic circumstance regarding the durability of dispersion paints. If small cracks form in the paint, large amounts of water can penetrate deep into the underlying rendering. Its evaporation, however, is then hindered by the high polymer content of the paint. As a consequence, the water content at the interface between rendering and paint increases steadily, thus destroying the outermost layer of the rendering. The paint layer, which responds strongly to temperature and humidity variations, soon delaminates from the powdering and sanding surface of the rendering.

In general, polymer-modified building materials show different aging behavior to regular mineral materials. This is caused by the longer water retention and an enhanced tendency for soiling, which is in particular exhibited by building materials with high polymer content. The problem of long-term compatibility of polymer-modified and regular building materials is exemplified by natural stone buildings for which after only a few years the polymer-containing repair mortars stand out from the facade as dark patches.

In spite of the small particle size, polymer dispersion are not appropriate for consolidating decayed natural stones or renderings. The polymer particles are retained at the surface, where they form an impermeable film. Only the water penetrates deeper into the pore space of the respective material. The polymer film lends the surface an undesired shiny appearance and prevents water-vapor transport. Moreover, the strength and the modulus of elasticity of the impregnated surface layer increase so that it is under risk to spall off.

9. Conclusions

Chemical conservation of buildings is a relatively new field of research. For this reason, long-term experience with the durability of polymers in contact with mineral materials is not available. There is no doubt that polymer additives can improve the workability of traditional materials and enlarge the area of their application. Likewise, chemicals can restore decayed stones and protect them from rain and frost. However, chemical building conservation is not just a theoretical science, but is strongly dependent on feedback from practitioners, and the rules of correct craftsmanship must always be respected. The feedback from practitioners helps to define aims of chemical research. Respecting the rules of good craftsmanship will help to avoid building mistakes which can not be repaired by chemical means. With respect to these considerations, refs. [89–91] can be recommended.

1. Introduction

In Western countries the awareness of the nutrition – health relationship among consumers and in the food industry increased sharply during the last 1990s. Several reasons for this increased awareness can be identified:

- Better knowledge on the nutrition – health relationship
- Increasing incidence of nutrition-related chronic diseases, mainly caused by the increasing average age of the population
- Increased purchasing power of consumers
- Increased knowledge in biological, immunological, and nutritional sciences
- Developments in food processing and food technology

New concepts in nutritional sciences have therefore been developed, e.g., functional foods or health value added foods (HVAF) [1]. HVAF refers to food that provides physiological or health benefits beyond the underlying basic nutrition [2] and is an important development in the prevention of chronic nutrition related diseases. It is associated with a shift of interest from health aspects of the total diet towards the health aspects of individual foods, without neglecting the importance of a balanced total diet [3], [4]. In Europe the potential of these foods was addressed in the European Union Demonstration Project (FAIR-CT96-1028: "Demonstration of Nutritional Functionality of Probiotic Foods"). New food ingredients with potential health benefits include dietary fibers and oligosaccharides (prebiotics); polyunsaturated fatty acids, antioxidants, vitamins, minerals, phytochemicals, and specific microorganisms (probiotics). Much scientific and public interest has focused on these probiotics [5–10]. Almost a hundred years have passed since the introduction of these theories of modulation of the intestinal ecosystem [11]. However, only recently has the scientific basis of probiotics been established and sound clinical studies on some bacterial strains published. The physiological and nutritional properties of some strains are now much better understood. Furthermore, it was possible to verify that some strains are probiotic with documented and well-published examples of their ability to maintain and promote the health of their host [12], [13].

2. Definitions

In order to clear the to some extend any existing degree of confusion how and when the different applied terminologies are used, the definition of several keywords should be introduced first. In market surveys, in the public printing-press and media, or even in the scientific literature, the different terms are sometimes used in place of another, without transferring the implied context. This is even more the case when we consider the excessive use of literal translations between the different languages. This can finally result in differing or unprecise definitions used by the regulatory authorities. In order to avoid this, we want to define some of the basic terms used in this article to contribute to a higher clarity of this text.

Health Value Added Foods. There is no universally accepted definition of HVAF foods so far. Nevertheless, a recent definition covers

this wide field to a great extent [1]: "a food can be considered as being functional, the moment it can be satisfactorily demonstrated that it affects beneficially one or more target functions in the host body, beyond an adequate nutritional effect, to improve the state of health or well-being, or reduces the risk of a disease". Not all of these claims are allowed in all countries, but it can neverthless be stated that functional foods have to go beyond the basic functions of enriched or fortified foods (e.g., vitamins, minerals). Consequently, a food containing a probiotic (i.e., a living bacteria) is a functional food. Furthermore, it must be possible to consume this foodstuff in quantities comparable and compatible with a normal, well-balanced, and varied diet.

Prebiotics are fermentable, non-viable food components (dietary fibers) that demonstrate a beneficial effect on the intestinal microflora of the host. This benefit to the host is mediated through a selective stimulation of the growth and/or activity of one or a limited number of species of the colonic microflora. As relevant substances, dietary fibers, lactulose, fructo- and galacto-oligosaccharides (FOS and GOS), and inulin (e.g., chicory extract) have been identified. They must not be hydrolyzed or absorbed in the upper gastrointestinal tract (GIT). They are either produced in-situ by bacteria or they are added exogeneously to the food [14]. In general they must alter the microbiota in the colon to a healthier composition and should induce luminal or systematic effects that are beneficial to host health. Bifidobacteria and/or lactobacilli are good target organisms [14], [15].

Probiotics are living microorganisms which, when ingested as a food supplement in sufficient numbers, exert a beneficial impact on the gastrointestinal balance and therefore a positive health impact that goes beyond the conventional nutritional effect [1], [16–20]. The most commonly used probiotics are lactic acid bacteria, such as lactobacilli or bifidobacteria, which are either added to fermented milk products, are responsible for the fermentation of the milk matrix itself, or are given as a supplement in a lyophilized form. Whilst the classical definition states that probiotics are living microorganisms, there is some new and on-going debate whether the concept should include dead microorganisms, or even bacterial fragments. So far, insufficient scientific data regarding their functionality is only available which would justify such an inclusion.

Synbiotics are a combination of a probiotic microorganism and a prebiotic substance. This mixture should benefit the host by improving the survival and implantation of the selected living bacteria in the gastrointestinal tract, by selectively stimulating the growth and/or by activating the metabolism of one or a limited number of health-promoting bacteria [14]. A combination of a bifidobacterial strain with fructose- or galactose-containing oligosaccharides for example, is a common and feasible approach. Only prebiotic bifidogenic factors have been concisely reported so far.

3. Prebiotics

The view of dietary carbohydrates as simply providing us with energy is outdated [21]. Because of their varied chemical and physical form, the rate and extent to which the different types are digested and absorbed in the small intestine varies. Dietary carbohydrates that escape digestion in the upper gastrointestinal tract form the predominant substrates for bacterial growth in the colon. This prebiotic approach offers a support for those probiotics which have insufficient survival rates and/or difficulties in colonization [22–24]. While some peptides, proteins, and certain lipids are potential prebiotics, nondigestible carbohydrates, including those that contain fructose, glucose, xylose and galactose, have received the most attention [21, 25, 26]. For a food ingredient to be classified as prebiotic, it must

1) Be neither hydrolyzed nor absorbed in the upper part of the gastrointestinal tract
2) Be a selective substrate for one or a limited number of beneficial bacteria commensals in the colon, which are stimulated to grow and/or are metabolically activated
3) Consequently, be able to alter the colonic flora in favor of a healthier composition
4) Induce luminal or systemic effects that are beneficial to host health [14].

Some nondigestible carbohydrates have a number of functional effects on the GI tract

which have been used to validate functional and health claims. These include delayed gastric emptying, modulation of GI tract transit times, improved glucose tolerance, reduced fat and cholesterol absorption via binding of bile salts, increased volume and water-carrying capacity of the intestinal contents, and modulation of microbial fermentation with increased short chain fatty acids (SCFA) production, and decreased pH and ammonia production [15], [25], [27]. The combination of these effects could potentially result in an improved host health by reducing intestinal disturbances (constipation and diarrhoea), cardiovascular disease, and intestinal cancer [15].

According to [15], the carbohydrate group that has received the most attention and research are the oligosaccharides. Fructooligosaccharides (FOS) have been extensively studied. A number of foods such as chicory, garlic, onion, artichoke, and asparagus contain relatively high concentrations of FOS [14]. FOS and other oligosaccharides can also be produced enzymatically, which is advantageous for large-scale commercial production [28]. In 1995, 12 food-grade oligosaccharides were in commercial production: lactulose, galactooligosaccharides, fructo-OS, isomalto-OS, malto-OS, palatinose-OS, glucosyl sucrose, cyclodextrins, soybean-OS, lactosucrose, gentio-OS, and xylo-OS. The prebiotic effect of these oligosaccharides is that they may selectively stimulate growth of bifidobacteria. Only glycosyl-sucrose, malto-OS, and cyclodextrins are not reported as being bifidogenic. According to different authors [29], [30] bifidobacteria seem to have a number of health-promoting properties such as improved intestinal environment, inhibition of pathogenic bacteria, immunomodulation, synthesis of vitamin B, improved calcium absorption, lowering of blood ammonia and cholesterol concentrations, and reported tumor formation in animal models.

Effects of feeding prebiotics to human volunteers. A wide number of studies have investigated the effects of FOS on human gut bacteria [15]. In general, feeding of FOS increases bifidobacteria and lactobacilli, increases SCFA concentrations and decreases clostridia, fusobacteria, bacteroides and pH [29], [31–33]. The selective fermentation of FOS by bifidobacteria has also been confirmed in-vivo in healthy human volunteers [14]. Moreover, when bifidobacteria grow on such substrates, they seemingly do so at the expense of bacteroides, clostridia or coliforms, which are maintained at low levels or may even be reduced [34]. The intake of FOS which have elicited a bifidogenic effect in human studies ranged from 4 to 15 g per day [25], [29], [35]. It is critical that the prebiotic effects are tested in properly controlled volunteer trials. Many bacteria are able to metabolize prebiotics in monoculture. However, the key-issue is their behaviour in a competitive ecosystem, such as occurs when feeding to healthy volunteers [15]. Some prebiotics, as inulin and oligofructose, have been reported to improve the bioavailability of some essential minerals such as calcium [36]. Upon inulin ingestion, the apparent Ca-absorption increased significantly. The increase of Ca-absorption did not negatively affect the absorption of other minerals such as magnesium, iron or zinc.

The advantage of prebiotics being carbohydrate materials is that it should be straightforward to incorporate prebiotics into common foodstuff such as cereals, biscuits, cakes, infant formula, weaning food, etc. without too much disturbing either the sensory qualities or texture of the product.

4. Probiotics

The word "probiotic" (Greek: "for life") has had many definitions in the past [16]. It was first used ca. 1965 to describe substances produced by one protozoan that stimulated the growth of another. Around 1970 it was used to describe tissue extracts that stimulated the growth of another tissue [37]. In 1974, Parker used the term to describe animal feed supplements: organisms and substances that have a beneficial effect on the host animal by contributing to its intestinal microbial balance [37]. Fuller (1989) defined the term probiotics in a way we basically still use nowadays as "a live microbial feed supplement which beneficially affects the host by improving its intestinal microbial balance" [37]. This revised definition stresses the importance of living cells as an essential component of an effective probiotic [38].

This definition was broadened to cover treatments with living bacteria that are not administered by mouth and that do not exert their effect through the intestinal microflora: "a mono- or mixed culture of live microorganisms, applied to man or animal as a fermented product or dried cells, that affects beneficially the host by improving the properties of the indigeneous microflora" [39]. This definition therefore includes probiotic products which exert these benefits in the mouth or gastrointestinal tract (taken as food or supplements), in the upper respiratory tract (administered as an aerosol), or in the urogenital tract (local application) [40].

The historical record of the probiotic properties of living microbial food supplements (particularly lactic acid bacteria) is long. As early as 76 B.C., PLINIO advocated the use of fermented milks in the treatment of various forms of gastrointestinal infections [41]. The effect of probiotics has been investigated since the early 1900s, before the term was even coined. One of the first to advocate that sour milk containing bacteria may have a positive effect on intestinal health and to provide an initial scientific explanation was MECHTNIKOFF in 1907 [11]. He proposed that the consumption of large quantities of yoghurt containing *Lactobacillus* spp. would result in the replacement of toxin-producing bacteria normally present in the intestine and thus result in better health and an increased lifespan. TISSIER (1906) had already proposed the administration of bifidobacteria to infants suffering from diarrhoea, believing that these bacteria would replace "putrefactive bacteria responsible for gastric upset, while re-establishing themselves as the dominant intestinal microorganism" [33], [42]. METCHNIKOFF believed that careful management of the gut microflora could exert beneficial effects on overall human health. In order to "manage" the gut microflora, he was particularly attracted by "exotic foods like kefir, yoghurt and sour milk" [43]. Nevertheless, it is impossible to state which bacterial species were present in these products at that time as they were still prepared in a very folkloristic way. Consequently, the majority of early research was (and is still) performed with microorganisms that are used to produce fermented milk products such as yoghurt. However, even in the early 1920s, researchers suggested that intestinal isolates might have better, more distinctive effects than non-intestinal organisms [16]. This idea is unfortunately not even today always considered in the selection of the wide variety of existing probiotic strains [15]. Recent well-documented clinical studies support health claims for specific bacterial strains, including *Lactobacillus johnsonii* La1 [44], *Lb. rhamnosus* GG [45], *Lb. casei* Shirota strain, *Lb. acidophilus* NCFB 1487, and *Bifidobacterium lactis* Bb12.

5. Selection Criteria for Probiotic Strains

There are a number of important properties that a bacterium must possess to make it a desirable candidate to become a probiotic [12], [40], [46], [47]. The bacterium must be able to survive the acidic conditions of the upper GIT, and proliferate in and/or colonize the intestine [48]. The absence of pathogenic, mutagenic, toxic, or carcinogenic effects on the host of its fermentation products or cell compounds must be assured. In addition, the probiotic bacteria could be antagonistic towards microorganisms involved in carcinogenicity and pathogenicity [49]. Furthermore, its genetic stability and the absence of a plasmid-transfer mechanism must be assured by means of conjugation experiments. Probiotic strains for humans should be of human origin, because some health-promoting effects might be species and origin dependant. They should be normal inhabitants of the intestinal tract, since this eases their adaption to the digestive system.

A classification of probiotic microorganisms and their infection potential follows [8]:

Lactobacillus	mainly nonpathogens, some opportunistic infections possible (usually in severely immunocompromised patients)
Streptococcus	oral streptococci mainly non-pathogenic (including *Str. thermophilus*); some may cause opportunistic infections
Enterococcus	some strains are opportunistic pathogens with hemolytic activity and even transferable antibiotic resistance (e.g., vancomycin)
Bifidobacterium	mainly non-pathogens, some isolated cases of human infections
Saccharomyces	mainly non-pathogens, some isolated cases of human infections

To be industrially applicable, the probiotic strain must be suitable for technological processes (easy to reproduce) and it must remain

viable during processing and storage in the final product or as a supplement.

Characteristics expected of potential probiotic strains are:

- Microbiological and safety parameters
  - Accurate taxonomic identification
  - Normal inhabitants of the target species (human origin)
  - Non-toxic and non-pathogenic and non-allergic
  - Genetically stable
  - Capable of survival, proliferation, and metabolically active at the target site
  - Potentially resistant to bacteriocins, acids, and other antimicrobials produced by the residing microflora
  - Resistant to bile salts
  - Resistant to acids, e.g., gastic juice
- Health benefits
  - Adherence and colonization potential preferred
  - High populations ($10^6 - 10^8$) per uptake
  - Antagonistic towards pathogenic/cariogenic bacteria
  - Production of antimicrobial substances (e.g. bacteriocins, hydrogen peroxide, organic acids)
  - Able to compete with normal microflora in a transient and/or permanent manner
  - Immunomodulatory
  - Able to exert clinically documented health benefits
- Industrial parameters
  - Stability of desired characteristics during culture preparation, storage, and delivery
  - Amenable to production processing: adequate growth, recovery, concentration, freezing, dehydration, lyophilization, storage, and distribution
  - Provision of desirable organoleptic qualities when included in the fermentation process

6. Physiological Effects, Clinical Applications, and Safety

A wide variety of beneficial functions of probiotic strains [59–61] have been reported or were theorized [62] (Table 1).

Table 1. Probiotic bacterial and yeast strains and their reported effects [12], [50–58]

Reported effects	Species [a]
Stimulation/modulation of the immune system [b]	*Lb. acidophilus, Lb. johnsonii, Lb. casei, Lb. plantarum, Lb. rhamnosus*
Balancing the intestinal microflora	*Lb. acidophilus, Lb. johnsonii, Lb. casei, Bif. lactis, Bif. bifidum*
Reduced fecal enzymes [c]	*Lb. acidophilus, Lb. casei, Lb. gasseri*
Antitumor	*Lb. acidophilus, Lb. casei, Lb. gasseri, Lb. plantarum, Bif. infantis, Bif. adolescentis, Bif. longum, Bif. lactis, Bif. bifidum*
Prevention of travellers diarrhoea	*Sacch. boulardii*
Prevention of rotavirus diarrhoea	*Lb. rhamnosus, Bif. bifidum, Bif. lactis*
Prevention of *Clostridium difficile* diarrhoea	*Lb. rhamnosus, Sacch. boulardii*
Prevention of other diarrhoea [d]	*Lb. acidophilus, Lb. rhamnosus, Lb. reuteri, Bif. bifidum, Bif. lactis*
Anti-Helicobacter activity	*Lb. johnsonii, Lb. acidophilus*

[a] *Lb = Lactobacillus, Bif. = Bifidobacterium, Sacch. = Saccharomyces;* only specific strains exhibit these characteristics; dairy strains of non-human origin and questionable high dosages (e.g., 500 g yoghurt per day) were not considered, due to unrealistic and unconventional dosages. [b] A variety of probiotic effects on the immune system have been reported. [c] Primarily those that convert non-toxic compounds into mutagens or carcinogens. [d] Including diarrhoea of viral origin and that caused by chemotherapy and antibiotic treatment.

Knowledge of the biological and clinical effects of various strains of probiotics is summarized in the following:

- Well established
  - Modulation of the immune system
  - Reduction of some diarrhoeal disorders (rotavirus, antibiotic effect, *E. coli* enterotoxin)
  - Anti *Helicobacter pylori* activity
  - Alleviation of lactose intolerance
  - Prevention of urogenitial infections
  - Alleviation of constipation
- Reasonably established
  - Improved resistance to intestinal infections and disorders
  - Change in fecal enzymatic activities
  - Improved nutritional value of food
  - Maintenance of normal intestinal and urogenital microflora
  - Protection against traveller's and infantile diarrhoea
  - Reduction of antibiotic-induced diarrhoea

- Suggested evidence: not yet clearly demonstrated and remains doubtful so far (only in-vitro or animal model data)
  - Reduction of serum cholesterol levels
  - Antitumour and anticancer activity
  - Vitamin production
  - Influence on hormone regulation
  - Prevention of hypercholesterolemia
  - Protection from colon/bladder cancer
  - Reduction of side effects of hepatic encephalopathy
  - Aid in hypo- and hyperchlorohydria
  - Prevention of osteoporosis

Adherence to human intestinal epithelial cells is considered a very important characteristic, since any probiotic strain which can become established, even only temporarily, is likely to have a competitive advantage and a greater or more prolonged probiotic effect. Adhesion to enterocytes and/or fecal colonization are important selection criteria for immunomodulation [63–66].

An important property of probiotic strains is their antagonistic activity against pathogenic strains by competitive exclusion, bacterial aggregation, or production of antimicrobial substances, including organic acids, hydrogen peroxide, and bacteriocins [67–70]. Although there is evidence that probiotic LAB reduce the risk of certain cancers in animal models, there is insufficient clinical data so far available to extrapolate these results to humans [71].

Interestingly, it was also discovered that the *Lb. johnsonii* La1 supernatant could significantly inhibit the *in-vitro* and *in-vivo* growth of the gastric pathogen *Helicobacter pylori* and other pathogens [53], [57]. A double-blind, controlled clinical study with *H. pylori* positive patients confirmed this result in the *in-vivo* situation, raising the question if and how far functional metabolites or bioactive molecules are involved [52], [53].

A critical evaluation of probiotics in the treatment of acute diarrhoea is difficult to prove in clinical practice, since many different probiotic microorganisms are used in different forms and in different combinations (yoghurt, milk, dried, etc.) [72]. The yeast *S. boulardii* is on of the probiotics with the most convincing and reproducible double-blind studies for an antidiarrhoea treatment so far. However, in some studies on bacteria it is not completely clear if the experiments were performed with viable cells or with their lysates. The effectiveness of bacteria in this aspect has to be more effectively demonstrated in well-designed randomized, placebo-controlled and double-blind studies before their large-scale use can be recommended [73], [74].

Requirements for good clinical studies with probiotic bacteria are [12]:

- Defined and well-characterized bacterial strains
- Well-defined studies and well-designed clinical trials
- Double-blind; placebo-controlled; randomized
- Results confirmed by different groups
- Publication in peer-reviewed journals

Probiotics are viable microorganisms, used in foods, especially fermented dairy products, but also in pharmaceutical preparations. The development of new probiotic strains aims at more active beneficial organisms [75], [76]. In the case of these novel microorganisms the question of safety and their risk-to-benefit ratio have to be assessed. Lactic acid bacteria (LAB) and Bifidobacteria have a long history of safe use in foods. Members of the genera *Lactobacillus* and *Bifidobacterium* are most commonly given the generally recognized as safe status (GRAS), whilst the genera *Streptococcus* and *Enterococcus*, and some other genera of LAB contain some opportunistic pathogens. Lactic acid bacteria are intrinsically resistant to many antibiotics, but in many cases these resistances are not transmissible, and these species are also sensitive to many clinically used antibiotics even in the case of LAB-associated opportunistic infections. Therefore, no particular safety concern is associated with intrinsic types of resistance. Plasmid-associated antibiotic resistance, however, which occasionally occurs, is another matter because of the possibility of the resistance spreading to other, more harmful species and genera. The transmissible enterococcal resistance against glycopeptide antibiotics (e.g., vancomycin) is particularly noteworthy, as vancomycin is one of the last effective antibiotics in the treatment of certain multidrug-resistant pathogens (e.g., staphylococci). New species and more specific strains of probiotic bacteria were identified in the last five years. Prior to incorporating these probiotic strains into

products their efficacy should be carefully addressed, and a case-by-case evaluation as to whether they share the safety status of traditional food-grade organisms should be made [8], [75], [77]. A theoretical side-effect of all probiotics is the risk of translocation into the bloodstream. All of the probiotics which are widely used in Western Europe and the United States appear to be safe. Only about 15 cases (mostly *S. boulardii* and *L. rhamnosus*) in a period of 10 years, during which millions of consumptions of probiotic-containing products or prescribed treatment of diarrhoea with yeasts, have been published in well-documented clinical cases in peer-reviewed scientific and clinical journals.

7. Outlook

Pre-, pro- and synbiotics are able to modify the intestinal microbial composition in the gastrointestinal tract. Dietary carbohydrates can no longer be viewed as simple energy providers only, the diversity of physiological and health effects need to be considered. It is only on this basics possible to understand the importance for health of probiotics for the human consumer [78]. Among the natural non-digestible oligosaccharides that fulfill the criteria of a prebiotic, FOS and inulin are the only products presently generally recognized and used as food ingredients. Other compounds with experimental evidence are, e.g., transgalactosylated disaccharides [79–82] and soybean oligosaccharides [83], [84].

The scientific literature reveals that probiotics offer a large number of theoretical advantages in the promotion of health beyond providing only basic nutritional aspects, justifying their attribute of being a HVAF. They offer a possibly partial solution to the problem of the increasing resistance of bacteria to antibiotics, and have the advantage of possessing multiple ways to express their effect. This makes it very unlikely that resistance to probiotics and their implied benefit might ever develop. They do not change the already existing intrinsic resistance of the intestinal colonizing microflora.

Numerous clinical trials have demonstrated that specific probiotic bacterial strains are able to deliver their health benefit, such as balancing the intestinal microflora, modulating the immune system or preventing gastrointestinal tract infections [85–88]. Many validated probiotic lactobacilli- or bifidobacteria-strains found naturally in the human intestinal tract have an excellent potential for a further inclusion into the functional food concept [44], [89]. In order to support health claims for pre- and probiotics, more collaborative data has to be created to associate changes in gut bacterial populations with the specific physiological aspects and changes in humans. Additionally, a better understanding of how pre- and probiotics cause changes in the microbial community is urgently required [31].

Particularly desirable effects described for various lactic acid bacteria are their activity against pathogens and strengthening the gut mucosal barrier [45], immune modulation [65], [66], anti-allergenic effects [90], anti-mutagenic and anti-tumorigenic activity, which have to be shown in more detail [50], [91], and further nutritional advantages [78]. In particular, the underlying molecular mechanisms for these probiotic properties need further scientific evaluation. Only the thorough demonstration of clinical and molecular effects by selected bacterial strains will give the probiotic concept its inherent credibility among the scientific community and consumers [13]. Given the ease of use, the consumer will be more attracted towards the concepts the more definitive health aspects are demonstrated, reported and proven [15]. The approach offers much potential in the prophylactic management of gastrointestinal diseases (such as inhibition of pathogens, prevention of bowel cancer or irritable bowel syndromes) and more systemic effects (e.g., potential reduction of blood lipids, potential hormonal regulation).

Future research on probiotic bacteria will most likely still center on the selection of new and more-specific strains of lactic acid bacteria (LAB) and other bacteria to promote the well-being of the host and which will fit into the definition of HVAF. Different regions of the gastrointestinal tract require different probiotic bacteria. Knowledge of the intestinal microflora is necessary in order to understand the impact of a probiotic strain on the microbial community in the intestinal tract [13], [31]. Dynamic models of the stomach, small intestine or colon to simulate the in-vivo gastrointestinal environment have been developed and validated and will provide a link between conventional in-vitro meth-

ods and in-vivo clinical and human studies. Furthermore, it will be necessary to select disease-specific strains, which could, for example, act against rotavirus diarrhoea or gastritis caused by *Helicobacter pylori*. Applications of molecular methods to the study of intestinal microbial ecology will help to achieve these research goals. Oligonucleotide probes targeting 16S ribosomal RNA have been used to study the microbial ecology [92], [93]. Other molecular methods used in molecular microbiology to determine unequivocally the effects of pre-, pro- and synbiotics on gut microbial ecology and to monitor microbial population changes include DNA-fingerprinting, 16S-rRNA restriction/amplified-fragment length polymorphism (RFLP/AFLP), and pulsed-field-gel-electrophoresis (PFGE).

Today, most probiotic strains are used in dairy products. Present studies indicate that new probiotic functional foods will include infant formulas, baby foods, fermented fruit juices, fermented soy products, fermented oatmeal without milk, and also disease-specific clinical foods containing viable and physiologically active probiotic bacteria. All these products will have to possess good stability and in many cases prolonged shelf-life. For such development to occur, it is important that the requirements for good clinical studies are followed even more carefully. In addition, the effects of mixtures of different probiotic strains should be investigated. With carefully controlled studies on clearly defined targets and well-selected strains the future will provide probiotic bacteria even more tailor-made for specific diseases and their subsequent prevention [12]. Information concerning both the individual bacteria and the complex microbial populations which are of intestinal origin will add to our overall knowledge of the ecology and activity of microorganisms in the gut intestinal tract and their relationship to our well-being [13].

1. Introduction

Membrane reactors (MRs) are finding use today in the petrochemical, water-treatment, food, and pharmaceutical industries. These reactor systems belong to a class of processes termed reactive separations, which combine reaction and separation into a single operation. The prime driver for such applications is the promise for savings in processing costs. In MRs the separation task is carried out by a membrane. The earlier applications of MR were in the catalysis field. Here combining the reaction and separation steps, in addition to providing process simplicity, also results in enhanced reactor selectivity and/or yield. Examples of such applications are equilibrium-limited reactions (e.g., hydrocarbon dehydrogenations), for which the continuous removal of a reaction product (e.g., hydrogen) often increases the reactor yield. Other examples include partial oxidation and esterification reactions. Some of the most promising MR applications today are in biotechnology, where MRs are used in industrially important biological reactions. These include fermentations used for the production of amino acids, antibiotics, and other fine chemicals. During such processes the membrane eliminates reaction metabolites that inhibit biological function and thus help to maintain high reactor productivity. Membranes are also increasingly being utilized in MRs as hosts for the immobilization of bacteria, enzymes, or animal cells for the production of highly value added chemicals. MRs are also finding increasing application in the treatment of contaminated air and water streams.

MR processes either integrate two physically distinct units – the reactor and the membrane module (Figure 1 a) – or incorporate both functions into a single unit (Figure 1 b). The compact design of Figure 1 b promises savings in capital and operating costs. Its downside is the loss of operational flexibility, as the reaction conditions may not be compatible with or optimal for membrane operation. MR applications (e.g., homogeneous catalytic applications) also exist in which the distinction in configuration is not clear.

There is a multitude of proposed configurations which combine the membrane and reactor into a single unit. For catalytic applications, Sanchez and Tsotsis [1] identified six such configurations, which are listed in Table 1 and shown schematically in Figure 2. The most common configuration is the PBMR, in which the membrane provides only the separation function. In catalytic applications, the reaction function is provided by a packed bed of catalyst particles placed in the interior or exterior reactor compartments. In the CMR configuration the membrane is itself catalytic, thus providing simultaneously the separation and reaction functions. To accomplish this for biological reactions, for example, enzymes or bacteria are grafted onto the membrane. Sometimes, the membrane used in the PBMR configuration is also itself catalytically active, often unintentionally so (frequently the case for metallic membranes), but, on occasion, purposely so to pro-

Figure 1. Different membrane reactor process configurations.

vide an additional catalytic function. The membrane reactor in this case is named PBCMR. For better control of the process temperature (important in the case of exothermic reactions), replacement of the packed bed by a fluidized bed (FBMR or FBCMR) has been suggested. In the CNMR configuration, the membrane is not typically permselective. It is only used to provide a reactive interface or as a contactor. Here the discussion is expanded to cover two other classes of membrane reactors. These are membrane bioreactors (MBR), in which the reaction is catalyzed by enzymes or whole-cell microorganisms, and pervaporation membrane reactors (PVMR), in which the separation task is carried out by a pervaporation membrane. For these membrane reactors both types of process configurations shown in Figure 1 are currently in use. For the process design which combines the membrane and reactor into a single unit, one could potentially identify a number of different configurations in analogy to those listed in Table 1 for the CMR.

Table 1. Classification of membrane reactors [1]

Abbreviation	Description
CMR	catalytic membrane reactor
CNMR	catalytic nonpermselective membrane reactor
PBMR	packed-bed membrane reactor
PBCMR	packed-bed catalytic membrane reactor
FBMR	fluidized-bed membrane reactor
FBCMR	fluidized-bed catalytic membrane reactor

Figure 2. Different membrane reactor configurations a) Shell side; b) Tube side

Though the first publications on MRs appeared in the late 1960s [2], [3], most of the progress in the area was made in the 1980s and 1990s [4], mirroring the state of the membrane field as a whole. In the field of catalysis, in particular, there has been a renewed interest in MRs in the 1990s, motivated by the development of stable microporous/dense inorganic membranes. These offer advantages over organic membranes, because they are stable at higher temperatures (> 373 K) and have good chemical and mechanical resistance [5], thus broadening the range of operating conditions for MR applications. This significant upturn in activity is reflected in the increasing number of

publications on catalytic MRs. Detailed descriptions have been published along the way. For recent accounts of the state of the art, see [6–8].

Both dense and porous membranes have found use in MR applications. Dense membranes are made of polymers, metals (mostly noble metals like Pd, Pt, Ru, Rh, Ir, and Ag) and their alloys, and solid oxides. Dense metal membranes (particularly Pd) were used in early applications [9]. They were used in the former Soviet Union by Gryaznov et al. [10–13]. They have high selectivity towards hydrogen or oxygen (Ag), but their high cost, relatively low permeability, and limited availability have hindered their extensive industrial application. There is also concern with their mechanical properties (embrittlement and metal fatigue) for applications requiring repeated thermal cycling at high temperatures. Ongoing efforts for improving the characteristics of these membranes [7], [8] involve depositing thin metallic films on underlying porous substrates with the aim of improving membrane permeance and cost without unduly impacting selectivity. Another type of dense membranes attracting attention in recent years [14] consist of solid oxides (ZrO_2, Y_2O_3, Bi_2O_3) and solutions of mixed solid oxides (perovskites, brownmillerites, etc.). These materials act as solid electrolytes that allow the transport of oxygen or hydrogen. They are finding use in catalytic MR applications involving partial and total oxidation reactions.

Porous membranes composed of glass, ceramics, or polymers, have also found use in MR applications. They are classified (IUPAC) as macroporous (average pore diameter $d_p > 50$ nm), mesoporous ($50 < d_p > 2$ nm), or microporous ($d_p < 2$ nm). Earlier studies made use of commercially available mesoporous membranes (Vycor glass; alumina, titania, or zirconia [15]). Recent efforts have focused on increasing the selectivity of these membranes towards small molecules. This has been accomplished by decreasing the mean pore size and/or narrowing the pore-size distribution of existing mesoporous membranes [8] or by synthesizing new microporous membranes (e.g., zeolite membranes [16]). Porous polymeric membranes have been the design choice in membrane bioreactors (MBRs); they have also been recently used for low-temperature catalytic applications [17].

2. Catalytic Membrane Reactors

2.1. Dehydrogenation Reactions

The catalytic dehydrogenation of light alkanes is a potentially important process for the production of alkenes, which are valuable starting materials for a variety of applications. The reaction is endothermic and is performed at high temperatures to improve the alkene yield, which is limited at lower temperatures by the thermodynamic equilibrium. Operation at high temperatures, however, results in catalyst deactivation, which requires frequent regeneration, and the production of undesired byproducts. Because of the promise of CMRs to overcome equilibrium limitations, this reaction was an obvious choice for MR applications from the beginning, and still remains the most commonly studied reaction. MR studies of light alkane dehydrogenation reactions to produce olefins have made use of both dense and porous inorganic membranes. Dense metallic membranes proved particularly succesful in the laboratory [18] because of their very high selectivity towards hydrogen, which eliminates reactant loss, a phenomenon that adversely impacts alkene yield for porous membranes. Their industrial applications have been hindered by problems of mechanical stability, high cost, limited commercial availability, poisoning by sulfur/chlorine impurities, and deactivation by carbon deposition. Some of the key studies are summarized in Table 2.

2.2. Hydrogenation Reactions

Catalytic MRs have also been applied to catalytic hydrogenation reactions, where the membrane's role is to separate the liquid from the gaseous reactant (e.g., hydrogen) and to provide a means for delivering this reactant at a controlled rate. Industrial applications of the technology have been reported for dense metallic membranes. They include the synthesis of vitamin K from quinone and acetic anhydride [34], and the hydrogenation of *cis*/*trans*-2-butene-1,4 diol to *cis*/*trans*-butanediol [35]. To provide a source of hydrogen, Gryaznov et al. proposed coupling through the membrane a catalytic dehydrogenation with a hydrogenation reaction.

Table 2. Membrane reactor applications for hydrocarbon dehydrogenation reactions

Hydrocarbon	Reactor type and membrane	Main results	Refs.
Ethane	600 – 873 K; Pt/alumina membrane or catalyst; composite membrane (PdAg alloy/glass); PBMR, PBCMR, CMR	20 % conversion increase over equilibrium	[19–21]
Propane	673 – 900 K, Pt or Cr_2O_3/alumina catalyst; PdAg, dense silica, or silica/alumina porous membranes; PBMR	conversion up to 3 times higher than equilibrium	[18], [22–25]
Isobutane or butane	723 – 823 K, PtSn or Cr_2O_3/alumina catalyst; dense silica, alumina, zeolite or composite (Pt/alumina) membrane; PBMR	isobutene yield up to 6 times higher than equilibrium	[26–30]
Cyclohexane	Pd metal, carbon hollow fiber; PBMR	conversions higher than equilibrium	
Ethylbenzene	800 – 973 K, Fe_2O_3 catalyst; alumina or composite (Pt/alumina, Pt/SS) membrane; PBMR	styrene yield up to 1.5 times higher than equilibrium; better selectivity	[31–34]

In this concept the dehydrogenation reaction on one side of the membrane produces hydrogen, which diffuses through the membrane and participates in the hydrogenation reaction [10], [12], [36]. This approach also provides a means for coupling the reactions energetically. Other novel concepts for providing hydrogen include integrating the hydrogenation reaction with H_2O electrolysis [37], [38]. In addition to dense metal membranes a number of recent studies also report the use of proton-conducting solid oxide membranes [39], [40] for hydrogenation reactions. Porous membranes have also been used for this type of reaction. For the reported applications the membrane acts both as a catalyst and as a contactor between the reactive phases. An advantage of the use of MRs for such an application are the decreased mass transfer limitations compared with the more traditional stirred-tank slurry reactor. Some of the key studies are summarized in Table 3.

2.3. Oxidation Reactions

Selective catalytic hydrocarbon oxidation is difficult to implement because the desired products are generally more reactive towards O_2 than the original hydrocarbons. One way to increase product selectivity is to control the O_2 concentration along the reactor length. This can be implemented by using an MR. The membrane allows the O_2 and the hydrocarbon to be fed in separate reactor compartments. With the membrane reactor the O_2 concentration along the reactor length can be controlled to influence selectivity, something not possible for fixed-bed reactors, for which the O_2 concentration is maximum at the entrance and decreases monotonically along the length. Therefore, for such reactors, the selectivity is low at the reactor inlet, where the reaction rate is the highest, and this adversely impacts overall yield. One potential additional benefit of membrane reactors for catalytic partial oxidation is that they provide for conditions less prone to explosions and other hazards typically associated with the oxidation of hydrocarbons [7].

The studies so far make use of both dense and porous membranes. Dense membranes consist of metallic silver (unique among metals in that it permeates oxygen) and its alloys, but most of the recent efforts make use of solid oxide membranes. The earlier such membranes were solid oxide electrolytes, like titania, yttria, calcia, or magnesia-stabilized zirconias (TiYSZ, YSZ, CSZ, MSZ) [45], [46]. These materials have good mobility of oxygen in the lattice but lack sufficient electronic conductivity, and this necessitates the use of an external circuit. Significant advances in this area have been made by the introduction of perovskites [47] and brownmillerites [48], [49], which have both good ionic and electronic conductivity and are also more thermally stable.

Oxidative methane coupling to produce ethylene and ethane has been investigated in solid-oxide MRs. Membranes used include TiYSZ, YSZ, CSZ, MSZ, doped Bi_2O_3, and oxygen- and proton-conducting perovskites with or with-

Table 3. Membrane Reactor Applications for hydrogenation reactions

Reaction	Operating conditions	Main results	Refs.
Vitamin K synthesis	400 K, Pd, Ni (tubular) membrane, CMR	yields up to 95 % in one step instead of 80 % in four steps	[34]
Cis/*trans*-2-butene-1,4 diol to *cis*/*trans*-butanediol	330 – 360 KPd, Ni or Pd – Ru (foil) membranes, CMR	up to 96 % yield of *cis*-butanediol	[35]
Cyclopentadiene hydrogenation	380 K, Pd – Ru composite ceramic – metal and metallic membrane, CMR	yields up to 1.3 times that of a batch reactor	[41]
α-methylstyreneto cumene	320 K, Pd/alumina membrane, CMR	cocurrent catalytic membrane reactor more efficient than a trickle-bed reactor	[42]
Nitrobenzene to aniline	320 K, Pt/alumina membrane, CMR	reactor effectiveness is strongly influenced by the configuration	[43]
Cinnamaldehyde hydrogenation	300 K, Pt/alumina membrane, CMR	modest increases in hydrocinnamyl alcohol production compared to batch slurry reactor (up to 1.1 times)	[44]

out the application of an external potential [6]. Though simulations [50] predict yields as high as 50 %, reported experimental yields so far, are less than 30 %, which is also the maximum yield obtained with packed-bed reactors [51]. The selectivity in the MR is reported to be higher than that in conventional reactors [52], [53]. Significant additional yield improvements would result [54] if the membranes could also simultaneously remove the C_2 product, but such membranes are currently not available [7]. Dense membranes have good oxygen permselectivity, which allows the use of air for oxidative coupling. However, their permeability is low, which limits reactor efficiency. This has motivated the use of porous membranes. Recent investigations using the PBMR configuration are encouraging. Using nonpermselective, commercially available alumina membranes and conventional oxidative coupling catalysts gave promising yields (ca. 25 %) [55–58]. An La-stabilized porous γ-alumina membrane in a PBMR packed with $Mn-W-Na/SiO_2$catalyst was reported to give higher C_2 yields [59] than those obtained with the more conventional co-feed configuration.

Another partial oxidation reaction attracting attention is synthesis gas production from methane. The earlier efforts made use of solid electrolytes [60], [61]. Integration of CH_4 partial oxidation with steam reforming in an electrochemical MR gave high syngas yields (97 %) [62]; the overall system is potentially thermoneutral. More recent investigations involve internally shorted metal/YSZ composites or single-phase mixed conductors [63], [64], which need no external circuitry. These materials have been shown to be stable after more than 500 h of synthesis gas generation. Collaborations by Amoco and the Argonne National Laboratory [65–69] used perovskite-like $Sr(Co,Fe)O_x$ materials and achieved conversion efficiencies of greater than 99 % and stable operation for over 900 h. Brownmillerite membranes [48], [49] also gave high yields and stable operation for over one year. Two U.S. industrial consortia were recently formed [8], [70] to commercialize solid-oxide MR-based synthesis gas production. One consortium, supported in part by the U.S. DOE., is led by Air Products and Chemicals, and includes Babcock and Wilcox, Ceramatec, Eltron, ARCO, Penn State University, and the University of Pennsylvania. This group has announced plans for an eight-year, $ 85 x 10^6 programme. The other group is an industrial alliance among BP/Amoco, Praxair, Statoil, SASOL, and Phillips Petroleum, also enlisting the help of a number of Universities including MIT, and the Universities of Alaska Fairbanks, Houston, Missouri-Rolla, and Illinois-Chicago. A third consortium with the same purpose seems to be in planning in Europe [8]. Despite these successes, concerns still remain about long-term materials stability in the high-temperature reactive environments [71]. Efforts to produce syn-

thesis gas by using a nonpermselective porous alumina membrane are also under way [72].

Other partial hydrocarbon oxidation reactions studied in membrane reactors include methanol and formaldehyde production from methane; the oxidative dehydrogenation of low molecular mass hydrocarbons, including ethane to ethylene, ethylene to acetylene, propane to propylene, and butane to butene and maleic anhydride; and selective oxidation of $C_2 - C_4$ alkanes into various oxygenates. A recent application involves the use of polymeric membranes in which active catalysts are incorporated as interfacial contactors to carry out partial oxidation (but also hydrogenation and hydroformylation) of various organic compounds [73], [74]. This concept allows the reaction to be carried out without a cosolvent, and prevents loss of catalyst. This was demonstrated, for example, for the oxyfunctionalization of *n*-hexane by H_2O_2 to a mixture of hexanols and hexanones by using titanium silicalite catalyst imbedded in a modified PDMS membrane [75]. Some key studies are listed in Table 4.

2.4. Other High-Temperature Applications

MRs have also been used for reactions of relevance to environmental protection. Such reactions include H_2S decomposition [110], [111]; NH_3 decomposition [112], [113], of potential interest in the treatment of coal gasification streams; and hydrodechlorination of dichloroethane [114]. For a number of applications in which the goal is full conversion of the pollutant and avoiding slippage out of the reactor, the membrane acts as a reactive interface between reactants flowing on either side. The concept was first demonstrated [115] for the selective catalytic reduction (SCR) of nitric oxide with ammonia. The membrane provided an interface for the nitric oxide to completely react with ammonia. The Claus reaction between hydrogen sulfide and sulfur dioxide [116], [117] and the oxidation of CO [118] and H_2S [119] were also studied in a CMR with a nonpermselective membrane. For these reactions, when the rate is fast, a sharp reaction front forms within the membrane and prevents reactant slippage from either side. Oxidative destruction of VOCs r [120–122] and photocatalytic oxidation of carbonyl compounds and bioaerosols [123] have been studied in a CMR. In this case, effective contact of the VOC with the catalyst is attained by forcing the VOC-containing gaseous stream through the membrane.

Steam and dry (i.e., CO_2) reforming of methane is one of the most important reactions for which membrane (porous and dense) reactors have been applied. Membranes prepared by coating thin Pd films onto mesoporous substrates by an electroless plating technique are currently being evaluated by Tokyo Gas and Mitsubishi Heavy Industries in membrane reformers in polymer electrolyte (PEM) fuel cell systems [124]. The same reaction was studied in a pilot plant scale FBMR system (Fig. 3) [125–127] which combines a fluidized bed of $Ni - Al_2O_3$ catalyst with a bundle of twelve tubular Pd membranes. Reactor performance was shown to be sensitive to the way in which the membrane area is distributed between the dense and dilute fluidized-bed phases. Methane and steam conversion enhancements were observed of up to 1.3 times that of the same reactor without a membrane. Despite the high installed membrane permeation capacity, the low permeability of Pd membranes still limited the conversion enhancement. Though membrane reformers have received significant attention, they have yet to be commercialized. Questions still remain regarding the effect that hydrogen removal may have on catalyst coking and H_2S poisoning of the membranes [128]. The overall economics still remain debatable, at least in the context of large-scale applications [129], [130]. Methanol membrane reformers for H_2 production have been studied [131], [132] in the context of mobile fuel cell applications. Potential benefits include reduced reactor volumes and a more compact unit design.

MRs combining the water gas shift (WGS) reaction and hydrogen separation in a single unit (WGSMR) are attracting attention in the context of the Integrated Gasification Combined Cycle (IGCC) plant, as a means to reduce CO_2 emissions. A study by a European academic and industrial consortium [133] concluded that the net efficiency of the WGSMR-integrated IGCC plant is 42.8 % (lower heating value = LHV) with 80 % CO_2 recovery, as opposed to 46.7 % (LHV) for an IGCC plant

Table 4. Membrane reactor applications for hydrocarbon oxidation reactions

Hydrocarbon and reaction	Operating conditions	Main results	Refs.
Methane oxidative coupling	1023 – 1123 K	Conversion up to 30 %	[53], [55–59], [76–88]
	YSZ, CSZ TiSZ, MSZ, Bi_2O_3, perovskites, Al_2O_3 or La_2O_3/Al_2O_3, and Pd – Ag membranes conventional oxidative coupling catalysts, Mn – W – Na/SiO_2 sometimes external electrical potential applied; CMR, PBMR, 2-stage PBMR	selectivity up to 97 %	
Methane partial oxidation to syngas	873 – 1273 K; CSZ, YSZ, perovskites, brownmillerite membranes; PBMR	conversion up to 99 %; selectivity to H_2 and CO up to 97 %	[48], [49], [61,62, 64–69], [89], [90]
Methane partial oxidation	573 K, zirconia – alumina or zirconia – calcia – alumina membrane; CMR	selectivity up to 96 %, generally low conversions	
to formaldehyde			[91], [92]
to methanol			[93], [94]
Ethane, oxidative dehydrogenation	700 – 900 K; TiYSZ, YSZ, Ce membranes	yields up to 7.5 %,	[77], [95], [96]
partial oxidation to oxirane and other oxygenates	Ag or V_20_5 catalyst; CMR, PBMR	conversion up to 6 times higher than equilibrium	[97], [98]
Ethylene partial oxidation to oxirane and other oxygenates	V_20_5/AL_2O_3; CMR, PBMR	higher yields than conventional reactors; unique selectivity behavior necessitates C_2H_4 distributed feed.	[80], [99], [100]
Propane, partial oxidation to propylene oxide	800 – 900 K; TiYSZ, YSZ, Ce, V_20_5/Al_2O_3 membranes	yields up to 7.5 % in epoxide	[22], [77], [97], [98]
oxidative dehydrogenation	Ag or V_20_5 catalyst; CMR or PBMR	yields up to 52 % in propene (1.4 times equilibrium)	[101–105]
Isobutane oxidative dehydrogenation	673 – 973 K, Pd membranes, Pt/Al_2O_3 catalyst	potential for autothermal operation	[107]
Butane, oxidative dehydrogenation	700 – 800 K; membranes: TiYSZ, YSZ, V_20_5/Al_2O_3	propene yields 1.7 times equilibrium	[77], [106]
partial oxidation to oxygenates including maleic anhydride	Ag or V_20_5 or VPO/catalyst; CMR or PBMR	anhydride yields up to 17.7 %	[97], [98], [108], [109]
Cyclohexane and dodecane partial oxidation to alcohol and ketones	298 K; PDMS membrane; zeolite-encapsulated iron phthalocyanine incorporated in membrane; CMR	higher turnover rates and selectivity with respect to homogeneous reactor	[73]
Cyclic alcohols (C_1, C_6, C_7) and 3-penten-2-ol epoxidation	298 K; PDMS membrane; zeolite-encapsulated iron-phtalocyanine and TDCPP(Mn)Cl complexes incorporated in membrane; CMR	higher turnover rates (9 ×) and selectivity (5 ×) than homogeneous reactor	[74]

without CO_2 recovery, and 40.5 % (LHV) with conventional CO_2 removal. Moreover, an economic analysis indicates favorable investment and operational costs. The study concluded that the WGSMR-integrated IGCC process is technically feasible, but further development in the area of high-temperature hydrogen separation membranes remains essential. Another application of the WGSMR is tritium recovery from breeder-blanket fluids in fusion reactor systems. The proposed process [134] uses two membrane reactors, the first of which removes the hydrogen isotopes from the purge gas (He) by oxidation, and the second is a WGSMR recovering tritium

Reaction	Operating conditions	Main results	Refs.
H_2S decomposition	773 – 1200 K; porous Vycor glass/Pt – SiO_2 – V composite dense membranes or ZrO_2 – SiO_2 membranes; sulfided Mo catalyst; PBMR	conversions up 3 × equilibrium at 1078 K (feed: 0.84 % H_2S in CH_4)	[110], [111], [135]
SCR of NO_x with NH_3	470 – 620 K; alumina and titania membranes impregnated with V_2O_5; catalytically impregnated fly-ash filter; CMR	Conversions of NO_x up to 70 %; selectivity to N_2 up to 75 %; simultaneous particle removal	[8], [115], [136]
NH_3 decomposition	700 – 900 K; Pd alloy or composite palladium – alumina membranes; PBMR	Conversion up 1.8 × equilibrium	[112], [113]
VOC oxidation	540 – 690 K; membranes: perovskite type (La-X-Y) on alumina tube or Al_2O_3; CMR	conversion up to 100 % , 1.7 times that of the monolith configuration	[120–122], [137]
Claus reaction between H_2S and SO_2	Al_2O_3, CMR	prevents slippage of reactants	[116], [117]
H_2S and CO oxidation	Al_2O_3, CMR	prevents slippage of reactants	[118], [119]
CH_4, steam reforming dry (CO_2) reforming	720 – 1000 K membranes: Pd or Pd/Vycor glass; Al_2O_3; CVD Pt, Ru/Al_2O_3. CMR, PBMR, FBMR	conversions up to 1.2 times equilibrium	[125–127], [138–143], [144], [145]

from tritiated water. Table 5 summarizes some key studies in this area.

3. Pervaporation Membrane Reactors

Pervaporation membrane reactors (PVMR) have attracted attention recently [146], [147]. Pervaporation (PV) has established itself as a practical technology in applications such as the dehydration of organic compounds, their removal/recovery from aqueous solutions, and the separation of organic mixtures. During PVMR operation the membrane removes either the desired (biotechnological/wastewater applications) or the undesired product (e.g., water from esterification reactions). Existing or proposed near-term industrial processes for application of PVMR include the production of ethyl and butyl acetate, ethyl and *n*-butyl oleate, diethyl tartrate, dimethyl urea, ethyl valerate, isopropyl and propyl propionate, and methyl isobutyl ketone.

The principal reactions studied by PVMR are esterifications. In the most common PVMR configuration the membrane and the reactor are housed in separate units (see Table 6). A number of commercial units are in operation [146], [147]. The process layout of a medium-sized esterification plant employing a PVMR, as described, for example, in [148], consists of a cascade of two reactors, each individually coupled to two PV units. Some earlier studies incorporated the membrane and reactor in the same unit [149]. Such a PVMR [150] was used to study the production of butyl oleate by lipase-catalyzed esterification with a hydrophilic cellulose acetate membrane. Conversion in the PVMR was 92 % compared to 61.1 % without PV. The economics of a number of process layouts involving PVMR have been discussed [151]. PVMR studies also exist for reactions other than esterification, including the production of dimethyl urea, methyl isobutyl ketone, and MTBE from methanol and *tert*-butyl alcohol (Table 6).

4. Membrane Bioreactors

Membrane bioreactors (MBRs) are a natural outgrowth of membrane applications in the food industry [160], which include the concentration of proteins from milk and the separation of whey fractions (e.g., lactose, proteins, minerals, and various fats). MBRs are finding increased use in bioengineering. Since the first MBR study on coupling UF membranes with a bioreactor [161], many other applications have been developed. MBRs are used today, for example, during biochemical synthesis to remove reaction products inhibiting biological function or to separate costly biocatalysts from the product stream for recycle (see Fig. 4). This increases cellular concentration, prolongs biocatalyst life, and increases the product turnover rate. Other MBR applications involve the hydrolysis of macromolecules (e.g., proteins), and enzymatic reactions which require co-factor recycling and the efficient delivery of one of the reactants.

In the simplest MBR applications, the membrane separates the products or metabolites of the reaction while retaining the biocatalysts, which are then recycled to the reactor. For whole-cell processes, microfiltration (MF) or ultrafiltration (UF) membranes are generally used to separate the biomass (average pore size 0.1 to several micrometers) from the product molecules. In enzymatic transformations UF membranes, with cut-offs ranging from 5000 to 100 000 Da, are utilized to retain the enzymes, whose molecular mass ranges from 10 000 to 100 000 Da. These simple MBR-based processes have been widely studied in the industry for the production of many chemicals, and efficiency improvements over the conventional bioreactors have been reported. In other MBR applications the biocatalyst is immobilized on the membrane itself. For whole-cell MBR it is fixed within the membrane's porous structure. For enzymatic MBR the biocatalyst is coupled to the membrane either by grafting (covalent or ionic binding or by cross-linking), gelation, physical adsorption, or by entrapment between the two skin layers of a porous membrane [162].

4.1. Whole-Cell MBR Applications

Coupling membrane separation with whole-cell (plant or mammalian cells, bacteria, or yeast) biocatalysis (fermentation, oxidation, etc.) is a common application of MBR. The production of lactic and propionic acid in a whole-

Table 6. Applications of pervaporation membrane reactors

Product	Operating conditions	Main results	Refs.
Butyl acetate	anion-exchange resin catalyst ;reactor and membrane separate units	PV replaces distillation; energy savings	[152]
Enzymatic esterification oferucic acid and hexadecyl alcohol	hollow-fiber membranes; reactor and membrane separate units	MR attains over 90 % conversion (vs. 53 % for conventional reactor)	[153]
Production of methyl isobutyl ketone	hydrophilic polymeric membrane; two reactors with the membrane unit in between	enhanced yield	[155], [156]
Butanol production	silicone membrane	improvements of 200 % in productivity	[154]
Dimethylurea production	PVA hydrophilic membrane; reactor and membrane separate units	removal of water allows recycle of CO_2 and amine resulting in reduced energy costs and by-products	[155]
Coating resins by polycondensation	Silica microporous membranes; reactor and membrane separate units	improved yield; membrane shows high water permeance and permselectivity	[157]
Esterification reactions of carboxylic acids and ethanol	hydrophilic polymeric membranes (PVA, polyimide, polyetherimide); reactor and membrane in same unit	significantly improved yields	[149–151], [158], [159]

Figure 4. Bioreactor coupled with an ultrafiltration (UF) unit

cell MBR using two different types of bacteria has been reported [163], [164]. Ethanol production was studied with *Saccharomyces cerevisae* [165]. Whole-cell MBRs have been utilized in a number of biochemical syntheses. An example used industrially is biosynthesis of growth hormone by the bacterium *E. coli* [166]. Other industrial examples include the synthesis of homochiral cyanohydrins [167], the production of L-aspartic acid [168], [169]. Naphthalene was oxidized to optically pure *cis*-1,2-dihydroxy-1,2-dihydronaphtalene by *Pseudomonas fluoroscens* [170]. Phenylacetylcarbinol, an essential intermediate for the production of the nasal decongestant ephedrine, was synthesized by using *Candida utilis* [171]. Whole-cell MBRs have also been applied to two-phase biotransformations, which are employed when one or more reactants and/or products have low solubility in water. In this case the membrane has a double function: it separates the two phases, thus avoiding the formation of an emulsion phase, and extracts the reactants from the organic phase and brings them into contact with the aqueous reaction phase. This type of reactor was used, for example, for the reduction of geraniol to citronellol (both poorly water-soluble) by *Saccharomyces cerevisiae* and the epoxidation of 1,7-octadiene by *P. oleovorans* [172].

In the perfusion hollow-fiber MBR, used for the synthesis of monoclonal antibodies, the cells grow in the extracapillary space (i.e., between the fibers). Nutrients circulating in the fibers themselves diffuse through the thin fiber skin to nourish the cells, while the metabolites are simultaneously extracted through the same hollow fiber skins [173]. Perfusion hollow-fiber MBRs mimic the function of the organs of living organisms, which also make use of a system of small capillaries. For mammalian cells (also called hybridomas) this type of MBR has been shown to support cell concentrations as high as 10^8 cells per milliliter [174]. These high cell concentrations result in highly concentrated antibody and protein harvests, with antibody harvests as high as 17 mg/mL [175], [176]. Such high yields and the relatively simple and inexpensive operation of hollow-fiber MBRs has made them an attractive choice in a number of commercial applications for production of monoclonal antibodies [173], [177]. Hollow-fiber MBRs have also been used for the production of a number of other fine chemicals, for example, the production of isovaleraldehyde from isoamyl alcohol using *Gluconobacter oxidans* [178]. Some of the most important whole-cell MBR applications are shown in Table 7.

4.2. Enzymatic MBRs

There are many important enzymatic reactions for which MBRs are finding application. In MBRs enzymes are often immobilized on the surface of the membrane or in its porous structure. Free enzymes and enzymes grafted onto a soluble polymer to increase their molecular size are utilized. In the latter case the membrane simply acts as a barrier to retain the enzymes, while allowing the removal of products and/or the addition of reactants. A key advantage of immobilization is that it permits easier enzyme recovery; in addition, grafting the biocatalyst sometimes increases its thermal stability and its resistance towards organic solvents.

MBRs are widely used in the enzymatic hydrolysis of macromolecules [165], [183]. They have been applied, for example, to protein hydrolysis and to enzymatic reactions requiring co-factor recycling [184], [185]. For the latter class of reactions, one of the earliest successes was L-phenylalanine synthesis from acetamidocinnamic acid utilizing NADH (β-nicotinamide adenine dinucleotide) as a co-factor [186]. Coenzymes like NADH act as co-substrates during the enzymatic reaction and, in so doing, they are converted into an inactive form. Since they are expensive ($ 1000/mol) they must be recovered for regeneration. In the above study [186], the co-factor was grafted onto a soluble polymer and separated by an UF membrane. Several studies involving this type of enzymatic transformation in MBRs have been reported [187]. L-*tert*-Leucine [188], erythrulose, [189] and (*S*)-2-octanol [190] have been synthesized in various MBR configurations.

Hydrolysis or transesterification reactions of lipids catalyzed by lipase and phospholipase are another reaction class to which MBRs have been applied. The enzymatic hydrolysis of olive oil by lipase was studied in a MBR using a hydrophobic membrane [191]. Lipase-catalyzed hydrolysis of olive and sunflower oils was also studied [192], [193]. MBRs have also found use in the

Table 7. Applications of whole-cell membrane reactors for biosynthesis

Reaction	Biocatalyst and type of MBR	Main results	Refs.
Alcoholic fermentation	*S. cerevisae*; inert membrane	conversion increases up to 3000 % with respect to a batch reactor	[114]
Growth hormone synthesis (hGH)	*E. coli*; inert membrane	yields by batch equivalent up to 40 000 extracted hypophyisis; hormone free of pathogens (e.g., Creutzfeld – Jacob syndrome)	[166], [179]
Propionic and lactic acid production	*P. bacterium*, *L. delbruecki*, inert membrane	conversion enhancement up to 1.6 times with respect to the stirred-tank reactor	[164]
β-amilase production	*Clostridium thermosulfurogenes*; inert membrane	yield up to 3000 % with respect to a batch reactor	[180]
L-Aspartic acid production	*E. coli*; inert membrane	maximum rate of production of 4.5 mol L^{-1} h^{-1}; industrial-scale process, continuous production for up to 30 d	[168], [169]
Isovaleraldehyde production	*G. oxidans*; inert membrane	conversion up to 90 %	[178]
Naphthalene oxidation to *cis*-1,2-dihydroxy-1,2-dihydronaphtalene	*P. fluoroscens*; inert membrane	production rate increases up to 300 % with respect to a batch reactor	[170]
Phenylacetylcarbinol synthesis	*C. utilis*; inert membrane	higher productivity and cell concentration (+ 300 %) with respect to a batch reactor	[171]
Antibodies synthesis	mammalian cells (hybridoma) immobilized on the membrane; also with an inert membrane	high cell concentration, good antibody productivity and purity; production up to 30 d continuously	[173], [177], [181]
Rifamycine B	*Nocardia mediterranei*, immobilized on the membrane	yield up to 1500 % with respect to a batch reactor.	[182]
Lactic acid	*L. rahmnosus*, immobilized on the membrane	conversion enhancement up to 1.6 times with respect to a stirred-tank reactor	[163]

production of polysaccharides. MBRs provide a simplified method for producing these materials, which are, typically, obtained in small quantities from natural sources by elaborate procedures. The synthesis of inulin (poly-β-(2,1)-fructose) in a MBR with the aid of fructosyltransferase immobilized in the porous structure of the membrane [194].

For enzymatic conversions, in particular, hollow-fiber MBRs are widely used, with enzymes typically immobilized in the porous structure of the hollow fibers. An advantage of these MBRs over the conventional bioreactors is the longer contact times of reactants with the enzymes, due to their high surface-to-volume ratios. Low residence times are a problem with conventional enzymatic bioreactors, and good efficiency is obtained only with rapid reactions. An example of the use of such a hollow-fiber MBR is the production of (2*R*,3*S*)-methyl methoxyphenylglycidate ester (2*R*,3*S*)-methyl methoxyphenylglycidate ester [(2*R*,3*S*)-MMPG], a chiral intermediate for diltiazem, an important calcium channel blocker used for the treatment of hypertension and angina. This MBR process was developed by Sepracor and was applied on an industrial scale by Tanabe Corporation in Japan. The reaction consists of the racemic resolution of the (±)-methyl methoxyphenylglycidate ester [(2*R*,3*S*)-MMPG + (2*S*,3*R*)-MMPG] by lipase, which is entrapped within the porous structure of hollow-fiber membranes, which separate an organic and an aqueous solution. Methoxyphenylacetaldehyde, which is an enzyme inhibitor, is also produced as a byproduct, but it is eliminated by adduct formation with bisulfite present in the aqueous phase [195], [196]. A schematic of the hollow-fiber MBR is presented in Figure 5. Some of the most important MBR applications are listed in Table 8.

A drawback of MBRs, especially when whole cells or bacteria are immobilized in the fiber pores, is biofouling, typically manifested by dra-

Table 8. Applications of enzymatic membrane reactors for biosynthesis

Reaction	Enzyme and type of MBR	Main results	Refs.
l-Leucine synthesis	l-leucine dehydrogenase and an enzymatic co-factor: NAD (grafted onto a polymer); inert membrane	high productivity (100 %) over a 7-week period	[197]
l-phenylalanine synthesis	acylase/L-PHEDH/FDH∗ and an enzymatic co-factor: NADH (grafted onto a polymer)	low deactivation rates of enzymes, and substrate conversion up to 90 %; continuous production for up to 60 d	[186]
Amino acids, enzymatic racemic resolution	acylase	15 – 20 t per month of l-amino acids	[198]
(2*R*,3*S*)-methyl methoxyphenylglycidate ester synthesis	Lipase imobilized on a membrane	commercial process (Sepracor, Tanabe); 75 t/a production	[195], [196]
Inulin (poly-β-(2,1)-fructose) synthesis	fructosyltransferase imobilized on a membrane	low-polydispersity product	[194]
Olive and sunflower oil hydrolysis and transesterification	lipase, phospholipase, imobilized on a membrane	high enzyme activity (up to 95 %) under steady state conditions	[189], [192], [193]

∗ (L-PHEDH) = L-phenylalanine dehydrogenase, (FDH) = formate/formate dehydrogenase

matic decreases in the permeate flow leading eventually, if left unchecked, to total plugging. The problem results because of adsorption on the membrane of metabolites that bacteria and cells produce, and of the coagulated proteins from lysed cells. The conventional solution to the problem is to stop the reaction, clean membrane, and sterilize the reactor. Critical to MBR success is the use of membranes and cleaning techniques appropriate for each type of reaction, in order to avoid irreversible plugging. In recent years many imaginative ideas have been proposed for in situ clean-up, and significant improvements in performance have been reported [199].

Figure 5. Schematic of the hollow-fiber, two-phase enzymatic bioreactor for the production of (2*R*,3*S*)-methyl methoxyphenylglycidate ester

4.3. Environmental Applications

Another application of MBR is in wastewater treatment, conventionally carried out by biological processes, transforming organic contaminants into harmless products, together with residual sludge. At some point the biocatalyst must be separated from the treated water. Biomass immobilization on porous supports (e.g., biofilters [200]) alleviates the problem somewhat. For heavily polluted waters, however, fast biomass growth clogs the beds and results in frequent shut-downs. MBR-based processes present a solution to the biomass/water separation problem, since membranes can provide a barrier for microbes and other particles, MBRs require a smaller volume than conventional systems, an important consideration in Europe and Japan. They allow for more effective process control, since the residence time in the fermentation vessel and the membrane permeation rate can be independently adjusted [201].

MBRs have been studied (e.g., Lyonnaise des Eaux in France) for the biological denitrification of drinking water and the anaerobic treatment of wastewater from the food industry. Challenges include membrane biofouling, and a large membrane flux to make the process economic, since the price of water is low and the volumes to be treated are enormous. Two notable commercial successful efforts include the Biosep process (OTV Industries, France [202]) and the Kub-

Table 9. Wastewater treatment units in France using the Biosep process (with permission of OTV Industries)

Company	Main activity	DCO treatment capacity, kg/d	Wastewater treatment capacity, m^3/d
Great Lakes Chemicals	Chemicals production	1500	300
Logimer	Food Industry	830	290
Lunor	Food industry	8000	540
Fabergé	Cosmetics	1300	300
Smart	Automobile	300	225
Dicosa (Pierre Fabre)	Cosmetics	2500	510
Faprogi (L'Oréal)	Cosmetics	9000	680
Papeteries du Rhin (Sonoco & Paul)	Paper production	3600	900

ota Process (Kubota Corporation, Japan [203]). Both systems consist of an aerobic bioreactor, with a hollow fiber bundle membrane immersed in the activated sludge, and air blown through the reactor bottom, creating agitation to improve reactor efficiency and diminish biofouling. Using hollow fibers, whose dense skin is on the outside in contact with the suspension, reduces the need for regular membrane back-washing The clean water is extracted by applying vacuum on the inner membrane side. A schematic of the process is shown in Figure 6.

This process has the advantage of generating very low quantity of sludge (with increased concentration and age) when compared with the more traditional biological treatment. Other advantages include its lower operating costs and, due to its compact design, a remarkable reduction in floor space requirements. Many units of different capacity have been installed in France, as indicated in Table 9.

5. Conclusions

Membrane reactors have and can be potentially applied to a broad range of processes, from the catalytic dehydrogenation of hydrocarbons, to hormone synthesis, to wastewater treatment. They are already commercial in low-temperature applications, like the biological production of fine, high-value chemicals, pervaporation, and wastewater treatment. These processes utilize commercially available polymeric and macro-/mesoporous inorganic membranes and have modest requirements in terms of membrane housing and sealing. High-temperature applications are not yet commercial, though good strides have been made in recent years, an example being synthesis gas or hydrogen production by partial oxidation or steam reforming of methane. Further advances here must await the development of more stable and affordable membranes, but the expected benefits are enormous given the size of the large-scale applications in the oil and petrochemical industry. One key hurdle for the application of membrane reactors to these industries is that existing processes are mature and highly optimized, with low a return on investment that does not provide much leeway in terms of initial capital investment. Membrane costs and availability are key factors here. Even for highly value added biological products, membrane capital investment is not negligible. For large-scale petrochemical applications such considerations remain the key factor hindering further progress.

1. Introduction

Polyureas are defined as polymers which contain ureylene groups –NHCONH– in the polymer chain. Urea, regarded as the diamide of carbonic acid, was first synthesized by Wöhler in 1892, but the chemistry and technology of polyureas have a more recent origin.

Linear polyureas are thermoplastic polycondensation products with aromatic (R = arylene) or aliphatic (R = alkylene) structures:

Polyureas or copolyureas with aliphatic structures exhibit a difference of 50 – 100 °C between the softening point and the onset of decomposition. They can be used as moldings. Polyureas and copolyureas with aromatic structures have softening points near their decomposition temperatures and are soluble in organic solvents, particularly in aprotic dipolar solvents such as DMF, *N*-methylpyrrolidinone (NMP), and DMSO. They are used for the preparation of lacquers, varnishes, and coatings [1]. The relationship between the softening points and structure is shown in Table 1.

Polyureas were first produced on a commercial scale at I.G. Farben by employing the reaction between diisocyanates and diamines. Mitsui Toatsu Chemical produces synthetic fibers from nonamethylenediamine and urea. Polyureas and copolyureas, particularly poly(urethaneurea)s, have many practical applications as foams, elastomers, fibers, etc.

Worldwide consumption was below 4.8×10^6 t in 1984 (in Europe, 2×10^6 t) and 5.9×10^6 t in 1995 [4]. More than 75 % of consumption was for foams [5]. Growth is estimated at 3 – 5 % per annum in the period 1995 to 2000. The number of products and producers continues to increase, and new processing technologies for thermosets, such as reaction injection molding (RIM), liquid injection molding (LIM), and others, are being developed.

2. Synthesis

The synthesis of polyureas is based on reactions between polyamines, especially diamines,

Table 1. Alternating copolyureas derived from diamines and diisocyanates

Diamine	Diisocyanate	Intrinsic viscosity, dL/g	Softening point, °C	Ref.
Piperazine	1,4-cyclohexylene diisocyanate	0.60	324	[2]
2,5-Dimethylpiperazine	1,4-cyclohexylene diisocyanate	0.48	390	[2]
2,5-Dimethylpiperazine	1,2-bis(4-isocyanatophenyl)ethene	0.33	362 (decomp.)	[2]
2,5-Dimethylpiperazine	bis(4-isocyanatophenyl)methane	1.30	350 (decomp.)	[2]
1,4-Phenylenediamine	bis(4-isocyanatophenyl)methane	0.36	400 (decomp.)	[2]
Hexamethylenediamine	4-methyl-1,3-phenylene diisocyanate	0.47	225 – 230	[3]

with aliphatic, aromatic, or heterocyclic structures and carbon dioxide, carbonyl sulfide, carbonic esters, phosgene, urea, urethane, and isocyanates.

From Diisocyanates and Diamines. Polyureas are readily prepared by a polyaddition reaction between diisocyanates and diamines.

Isocyanates are reactive products, and the reactivity toward compounds containing active hydrogen is as follows: $RNH_2 > ArNH_2 >$ primary OH > water > secondary OH > tertiary OH > phenolic OH > COOH > RNHCONHR′ > RCONHR′ > RNHCOOR′ [6]. An isocyanate group bonded to an aromatic ring is more reactive than one bonded to an aliphatic chain. Many aliphatic amines are extremely reactive with isocyanates, even at low temperatures. Relative reactivities of amines with phenyl isocyanate in diethyl ether at 0°C [7] follow:

NH_3	1.00
Ethylamine	9.72
n-Propylamine	8.22
n-Butylamine	9.17
n-Amylamine	9.17
Aniline	0.53

Secondary aliphatic and primary aromatic amines react similarly. Secondary aromatic amines are less reactive [7].

For the amine – isocyanates reaction, the following mechanism has been proposed [8]:

In this mechanism, HM is a proton acceptor/donor, for example, an amine, urea, or carboxylic acid, which acts as catalyst [9]. The reactions between isocyanates and amines are usually autocatalytic, but they can be catalyzed by many other catalysts, amines, or acids [10], [11].

Weak aromatic carboxylic acids show a high catalytic activity [12]. In benzoic acid derivatives, electron-acceptor substituents such as NO_2, Cl, or OH reduce catalytic activity, whereas electron-donor substituents such as alkyl groups increase it; 2-methylbenzoic acid is the most active catalyst.

Lewis bases such as 1,4-diazabicyclo-[2.2.2.]-octane (DABCO), triethylamine, dimethylbenzylamine, and pyridine also exhibit catalytic activity. 4-(Dimethylamino)pyridine is an exceptional catalyst, not only in reactions with amines (strongly nucleophilic reagents), but even with alcohols (weakly nucleophilic reagents) [13]. For reactions with alcohols, the following mechanism has been proposed [14]:

Insertion catalysts such as dibutyltin dilaurate, tin(II) octanoate, and cobalt naphthenate have also been used in this field [15].

The effect of substituents on the reaction between aromatic isocyanates and aromatic amines has been studied [10]. The reaction rates were determined by refluxing 0.005 mol substituted phenyl isocyanate and 0.005 mol substituted aniline for 1 h in a mixture of toluene and benzene. The urea yields are shown in Table 2.

The effect of substituents on the reactivity of the isocyanate decreases in the order: 2,4-$(NO_2)_2$ > 3,5-$(NO_2)_2$ > 4-NO_2 > 3-NO_2 > 2-NO_2 ≫ H, 4-CH_3, 3-OCH_3, 4-OCH_3. Electron-acceptor substituents in aromatic isocyanates increase the reaction rate. The same substituents in aromatic amines reduce the reaction rate. Steric hindrance is also influential. *Ortho* substitution in aromatic isocyanates or amines reduces the reaction rate.

The reaction between diamines and diisocyanates is usually carried out by interfacial polyaddition [16] or in solution [17]. In the bulk, infusible, insoluble cross-linked polymers can be obtained instead of the desired linear polyureas. Cross-linking occurs by the interaction of the highly reactive free isocyanate groups with active hydrogen atoms from the urea groups [18]. The most important application of this reaction is the synthesis of poly(urethaneurea)s, also called copolyureas.

Another interesting application for polyureas is in nonlinear optics (NLO); the NLO response of polyureas is extremely rapid, because effects occur primarily through electronic polarization [19]. It is now well-known that molecules containing electron-donor and electron-acceptor groups separated by a large conjugated π framework possess large values of second-order molecular hyperpolarizability [19]. For the synthesis of polyureas with these properties, 4-(dialkylamino)-4′-(alkylsulfonyl)azobenzene NLO chromophores have been used, which contain methylsulfonyl groups as electron-acceptor groups, 4-dialkylamino groups as electron-donor groups, and between them azo groups [20–22].

Another interesting application is the synthesis of hyperbranched polyureas (Fig. 1) [23], which have unusual properties [24].

In these syntheses, the most important monomer is 3,5-diaminobenzoyl azide (**4**), which on heating in NMP at 110 °C under argon for 16 h gives unstable 3,5-diaminophenylisocyanate (**5**) and finaly hyperbranched polyureas. Curiously, these hyperbranched polyureas are soluble in aprotic dipolar solvents such as DMSO, NMP, and DMF.

From Diisocyanates and Water. Polyureas can be prepared from diisocyanates and water:

The diamine resulting from reaction of water with the diisocyanate reacts with unconverted diisocyanate more rapidly than water, and polyureas are obtained in high yields. The reactivity of water with diisocyanates is similar to that of secondary alcohols [10]. This apparently simple reaction is, in fact, quite complicated:

Scheme 1. Synthesis of hyperbranched polyureas

Table 2. Urea yields from aromatic isocyanates and aromatic amines

Isocyanate substituent	Amine substituent								
	2,4-$(NO_2)_2$	2-NO_2	3,5-$(NO_2)_2$	4-NO_2	3-NO_2	3-OCH_3	H	4-CH_3	4-OCH_3
4-OCH_3	–	–	–	–	15	91	90	95	98
4-CH_3	–	–	–	3	14	90	95	98	–
H	0	0	0	0	26	92	92	100	–
3-OCH_3	–	–	–	0	46	95	–	–	–
3-NO_2	0	0.5	4	13	52	96	100	–	–
4-NO_2	0	4	8	14	61	97	100	–	–
3,5-$(NO_2)_2$	0	8	16	54	76	95	100	–	–
2-NO_2	0	0	1	8	60	98	100	–	–
2,4-$(NO_2)_2$	0	45	51	76	84	87	100	–	–

Route (a) is favored when the carbamic acid is stable and reactive toward the isocyanate [25]. Route (b) is favored when the carbamic acid is unstable and decomposes to an amine, which reacts quickly with the isocyanate. Route (c) is favored when the reaction between the carbamic acid and amine is faster than the reaction between the amine and isocyanate. The effect of substituents on the reaction of aromatic isocyanates with water is similar to that observed in the reaction of aromatic isocyanates and amines.

This simple reaction is employed in the manufacture of foams, in which the resulting carbon dioxide acts as a foaming agent. Different amines or amine complexes of metal salts are suitable catalysts for this reaction [26]. With tertiary amines, the following mechanism is proposed [27]:

From Diamines and Carbon Dioxide or Its Derivatives. The polycondensation of diamines and carbon dioxide or its derivatives gives polyureas in high yields (X = halogen, OR, NH_2, etc):

Polyureas are obtained by the polycondensation reaction of *carbon dioxide* and diamines in the presence of diphenyl phosphite in pyridine at 40 °C and 2 MPa. This reaction involves a carbamoyloxy-*N*-phosphonium salt of pyridine as intermediate [28]:

Ethylene chlorophosphites with aliphatic structures are also suitable reagents for this reaction under mild conditions, the mechanism of which involves a four-center transition state [29]:

Without catalysts, the reaction of carbon dioxide with diamines requires high temperatures and high pressures [30].

Polycondensation of *phosgene* (carbonic acid dichloride) with diamines gives polyureas [31]. Similarly, *bis(carbamyl chloride)s* prepared from diamines and phosgene, can react with diamines of similar or different structures to afford polyureas (a) or alternating copolyureas (b), respectively:

From aliphatic or aromatic diamines and *urea* at high temperatures, polyureas result with the evolution of ammonia. This reaction can be carried out in the melt [32] or in solution [33].

Diphenyl carbonate does not react with aromatic amines in boiling toluene, but the addition of $MgCl_2$ as catalyst in pyridine makes this reaction possible at 120 °C [34]. The same reaction is also possible in phenol or cresol, but at 210 – 230 °C [35]. Activated *carbonic esters*, such as bis(*p*-nitrophenyl)carbonate or bis(2,4-dinitrophenyl)carbonate, can react with diamines at low temperatures to afford polyureas with high viscosities [36]. The rate of reaction is higher for aliphatic diamines than for aromatic diamines [37].

By Other Methods. Diamines can react with *N*, *N′*-carbonyldiimidazole in THF under reflux to give polyureas [38]. Polyureas with moderate molecular masses were prepared by the condensation reaction of lithium carbonate with aromatic diamines in presence of triphenyl phosphite and hexachloroethane in pyridine under reflux [39]. By using the same reaction, polyureas with high thermostability result from 2,8-diaminobenzothiophene or 2,8-diaminophenoxanthine and lithium carbonate [40].

A simple and ingenious method involves a controlled decomposition reaction of sebacoyl diazide in water to form poly(*n*-octylurea) [41].

In an interesting reaction, palladium diacetate catalyzes oxidative polymerization reactions of aliphatic diamines $H_2N(CH_2)_nNH_2$ ($n = 4, 6, 8, 10, 12$) with carbon monoxide in presence of potassium carbonate, triphenyl phosphite, and iodine to afford polyureas [42].

Poly(*N,N′*-diacylurea)s have been obtained by polyaddition reactions of diamides to bis(*N*-acylisocyanate)s [43].

3. Polyureas as Starting Materials for Other Polymers

Polytriketoimidazolidines. Polymers with this structure in the macromolecular chains were prepared by reactions between various polyureas and oxalyl chloride in the presence of pyridine [44]; they decompose 70 – 100 °C higher than the corresponding polyureas.

Polyhydantoins. Aromatic polyhydantoins of high molecular mass have been prepared by a polyaddition/cyclocondensation reaction of diethyl *m*-phenylenebisiminoacetate and aromatic diisocyanates in cresol under reflux [45]:

The polyhydantoin obtained from methylenebis(4-phenylisocyanate) is stable in air up to 400 °C. Aspartate polyhydantoin prepolymers can react with blocked polyisocyanates to give products that are useful for coatings, adhesives, and elastomers [46].

Polyquinazolinediones. The reaction of 3,3′-benzidinedicarboxylic acid and diisocyanates with triethylamine as catalyst and NMP as solvent results in polyureas, which are cyclized by heating at 220 °C to polyquinazolinediones [47]:

Polyhydrouracils can be obtained by the cyclization of 2-carbomethoxyethyl-substituted polyureas with polyphosphoric acid (PPA) [48]:

Polyhydrouracils decompose at 400 °C; analogous unsubstituted polyureas decompose at 300 °C.

Other Polymers. Poly(imideurea) elastomers with high elasticity and improved thermostability can be obtained by reaction of polyureas $(R^1NHCONHR^2NHCONH)_n$ with aromatic tetracarboxylic dianhydrides (R^1 = aromatic or aliphatic diisocyanate residue; R^2 = oligomer residue containing amino group-terminated elastomer segment; $n = 2 – 500$) [49].

Heat-resistant polycarbodiimide copolymers for electric cable insulation can be prepared from urea copolymers and 3-methyl-1-phospha-3-cyclopentane-1-oxide as dehydrating agent [50]. The resulting copolymers have high thermostability (at 331 °C, losses are 5 %). Soft Cu conductors were coated with these polycarbodiimides with excellent results.

The end groups of aliphatic polyamides can react with polyureas at high temperatures (200 °C) to give copolymers that exhibit improved fiber dyeability [51].

4. Homopolyureas

Homopolyureas, $[NHCOHN(R)]_n$ have polar structures and high softening points. Homopolyureas with aromatic or heterocyclic structures

have softening points higher than those with aliphatic backbones. The introduction of a symmetrical 1,4-phenylene ring into the polymer chain raises the softening point. *N*-Alkylation lowers softening points. Aliphatic homopolyureas have softening points of about 200 °C and they can be injection-molded, extruded, and processed like other thermoplastics.

5. Copolyureas

Copolyureas have the general formula $[NH(R)NHCONH(R^1)NHCO]_n$, where R and R^1 can be aliphatic, aromatic, or heterocyclic and contain phosphorus, sulfur, silicon, or halogens (simple copolyureas). Copolyureas may contain other functional groups, such as urethane, amide, imide, carbonate, etc.

5.1. Simple Copolyureas

Copolyureas Containing Silicon. Thermostable polysilylureas with good flexibility have been obtained from diamines $H_2N–R^1–NH_2$ and $O[SiR^2(CH_2)_nHCO]_2$ (where $n = 1 – 3$, R^1 = alkyl or aryl, and $R^2 = CH_3$ or C_6H_5) [52]:

Also, from 1,3-bis(chloromethyldimethyl)siloxane and KOCN the corresponding Si-containing diisocyanate results, which reacts with diamines [53].

Copolyureas Containing Phosphorus. Polyphosphorylureas are prepared from aryl or alkyl phosphoric diisocyanates and diamines by interfacial polyaddition [54]:

Polyphosphorylureas in which R is C_6H_5 and R′ is *m*-C_6H_4 have a 10 % weight loss at 400 °C and a 40 % weight loss at 600 °C. Flame-retardant copolyureas useful for foams or films are prepared from 1-[(dialkoxyphosphinyl)methyl]-2,4-diaminobenzenes and diisocyanates in NMP at low temperature [55]. By similar methods, phosphorus-containing copolyureas have been prepared from phenyl bis(piperazidophosphate) and diisocyanates [56].

Copolyureas Containing Halogens. Heat-resistant, flame-retardant copolyureas are prepared from fluorinated primary diamines and diisocyanates [57]:

R = alkylene or arylene; *m* = 2 - 4

These copolyureas are useful for oil-resistant coatings and as curing agents for epoxides. Other halogen-containing diamines, such as 1,1,1-trichloro-2,2-bis(4′-chloro-3′-aminophenyl)ethane [58] or 1-(tetrafluoroethoxy)-2,4-phenylenediamine [59] can be used in reaction with diisocyanates, to afford flame-retardant copolyureas.

Copolyureas with Acid or Ester Groups. Polyurea electrolytes are prepared from sodium 3,3′-benzidinedicarboxylate and diisocyanates in the presence of sodium laurate as catalyst [60]:

R = alkylene or arylene

From L-lysine diisocyanate methyl ester and optically inactive diamines, optically active copolyureas have been prepared [61]:

$m = 2 - 6$

Optical studies on these copolyureas revealed that they contain macromolecules with different conformations, ranging from disordered to helical [62]. Treating the polyureas with trifluoroacetic acid causes rupture of hydrogen bonds and reduces the ordering. These polymers can be degraded by chymotripsin or subtilisin [63]. An interesting method for the preparation of these copolyureas involves the polycondensation of L-lysine with 4,4′-dinitrophenylcarbonate [64].

Other Simple Copolyureas. Polycyanoureas with high molecular masses are prepared by a polyaddition of 3,3′-dicyano-4,4′-oxydianiline and diisocyanates in NMP with triethylamine as catalyst [65].

Thermostable copolyureas with oxadiazole rings in the main chain are prepared from bis[5-(3-aminophenyl)-1,3,4-oxadiazol-2-yl]alkanes and diisocyanates in DMF at 60 °C [66].

Polyverdazyl – polyureas are prepared from 1,4-bis[(1,5-diphenyl)-3-(4-aminophenyl)verdazyl-6-yl]butane and diisocyanates [67].

Triazine [68], carborane [69], and ferrocene [70] copolyureas also have high thermostability.

Copolyureas containing crown ethers (cryptates) are used as phase-transfer catalysts for alkylation, esterification, and oxidation. The copolyurea prepared from *trans*-Ar,Ar′-diaminodibenzo-18-crown-6 and TDI has a potassium ion absorption of 45 mg KOH per 100 g polymer, compared to 0.02 mg for the diamine monomer [71].

5.2. Copolyureas Containing Other Functional Groups

Poly(urethaneurea)s are the most important class of copolyureas. They can be prepared from a macrodiol (polyester diols, polyether diols, etc.) and an excess of a diisocyanate; this results in prepolymers with NCO end groups, which react with diamines (chain extenders). At the end of the reaction, a chain terminator (ROH, $RHNH_2$) is added [72], [73] (see below).

In the scheme presented above, the NCO – NH_2 polyaddition reaction is much more rapid than the NCO – OH polyaddition reaction and requires no catalysts. This rapid curing results in short production cycles.

Prepolymers with NCO end groups can also react with water, whereby the resulting carbon dioxide byproduct is used as a foam-

R, R′ = alkylene, arylene, heterocycle, etc.

ing agent in the production of poly(urethaneurea) foams. Poly(urethaneurea) copolymers have many practical applications as foams, cellular elastomers, fibers, aqueous dispersions, etc.

Optically active poly(urethaneurea)s were synthesized by solution polyaddition of (1*S*,2*S*)-(+)-2-amino-3-methoxy-1-phenyl-1-propanol with diisocyanates [74].

Poly(urethaneurea)s obtained from D-glucosamine and diisocyanates also have optical activity [75]. These polymers absorb 10 – 24 % water, whereas the poly(urethaneurea)s prepared from $HO(CH_2)_5NH_2$ and diisocyanates are almost non-hygroscopic; acetylation reduces the hygroscopicity.

Light-resistant poly(urethaneurea)s are prepared from 1,3-bis(isocyanatomethyl)adamantane and polyester diols with diamines as chain extenders [76].

Poly(urethaneurea)s with ionic links in the main chain were synthesized from MDI or 2,4-TDI and 4-hydroxybutyl phthalate as salts with divalent metal ions such as Ca^{2+}, Mn^{2+}, and Pb^{2+} [77].

Poly(AmideUrea)s. Aromatic poly(amideurea)s are prepared from 4-isocyanatobenzoyl chloride and diamines [78] and from 4,4′-diaminocarbanilide and $R(COCl)_2$ [79]:

R^1, R^2 = alkylene or arylene

These poly(amideurea)s have excellent thermal stability and good solubility in aprotic dipolar solvents.

Thermostable poly(amideurea) acids can be prepared from 4,4′-diaminodiphenyl ether, pyromellitic dianhydride, and diisocyanates, which can be used as intermediates in the syntheses of poly(imideurea)s [80]:

Poly(imideurea)s with improved thermal stability are obtained from pyromellitic dian-

R – arylene

hydride and *N,N′*-dimethyl-*N,N′*-bis(4-aminophenyl)urea [81], or from the same dianhydride and $H_2N(NHCONHR)_mNH_2$, where R is $-(CH_2)_{12}-$; $-C_6H_4OC_6H_4-$-, $-C_6H_4CH_2C_6H_4-$-, or $-C_6H_4SO_2C_6H_4-$ [82]:

Sequential condensation can result in poly(imideurea)s with thermal stability up to 380 °C (see below).

These poly(imideurea)s can be cyclized to polyiminoquinazolinediones.

Poly(carbonateurea)s can be prepared from bis-(4-aminophenyl) carbonate and diisocyanates (a) [83], or from *p*-isocyanatobenzoyl chloride and hydroquinone, which give a monomer with NCO end groups (b) that reacts with diamines [84] (see top of the next page).

These poly(carbonateurea)s have properties similar to these of aromatic polyureas, but exhibit higher solubility.

6. Structure

The structure of polyureas and copolyureas controls their chemical and mechanical properties.

Poly(urethaneurea)s contain hard and soft segments. Usually, the hard segments have an aromatic structure and the soft segments an aliphatic structure. During solidification from solution or melt, the hard and soft segments undergo phase separation, which results in elastomeric properties. The properties of poly(urethaneurea)s depend largely on the extent of phase separation, which is due to thermodynamic incompatibility [85]. Compositional variables, such as symmetry in the diisocyanate structure [86], chain extenders, aromatic or

aliphatic diamines [87], molecular mass distribution of the soft and hard segments [88], cross-linking [89], and hydrogen bonding [90], have a strong influence on the extent of phase separation.

In each urethane or urea linkage, the NH and CO groups act as proton donor and proton acceptor, respectively. Since the urea group is more polar than the urethane group, the separation of hard and soft segments is more marked, the melting range of the hard segment domains is higher, and the intermolecular (interchain) interactions are stronger. The urea carbonyl groups are considered to be completely hydrogen-bonded [91]; this feature is probably responsible for the increased phase separation in poly(urethaneurea)s.

The presence of hard segments is responsible for the high tensile strength and modulus exhibited by the materials derived from these copolyureas. The soft segments determine the thermoplastic behavior.

Phase separation has been proved by electron microscopy [92], small angle X-ray scattering [93], differential scanning calorimetry [94], and other methods [95]. The same phenomenon was studied by advanced solid-state NMR spectroscopy; the sizes of various domains and the interfaces between them were quantified by spin measurements. Also, the impact of annealing, method of polymerization, and hard segment content on the properties of poly(urethaneurea)s were studied. Major tranformations have been observed after annealing at 190 °C, when the system behavior changes from "soft in hard" to "hard in soft". The highest microphase separation is observed in solution-polymerized samples. These NMR experiments reveal the nonequilibrium nature of RIM systems for poly(urethaneurea)s [96]. For the same system of RIM poly(urethaneurea)s, FT-IR spectrophotometric data suggested that an increase in degree of phase separation and a decrease in the size of hard-segment domains take place with increasing catalyst concentration [97].

Problems of structure arise in the field of polyureas and poly(urethaneurea)s expanded by water for foams. The reaction of isocyanate groups with water to give urea groups can be monitored by IR spectroscopy at 1646 cm^{-1} for carbonyl groups and 3300 – 3320 cm^{-1} for

NH groups [98]. The absorption of the carbonyl group from polyureas is not restricted to the region around 1640 cm^{-1} and varies within wide limits according to the degree of association [99]. A band at 1695 cm^{-1} has been attributed to an unassociated urea group in polyureas [100]. The NH absorption at 3320 cm^{-1} indicates that most of the NH groups are hydrogen-bonded, because the free-NH absorption at 3445 cm^{-1} is negligible [91]. This polar structure can be represented by the following structures:

R, R' = arylene, alkylene, etc.

The high melting points, thermostability, and crystallinity of polyureas may be due to the partial polar structure.

The capacity for hydrogen bonding between urea groups and solvents is as follows: alcohols $\gg$ THF > $CHCl_3$ > toluene [101].

7. Properties

7.1. Physical Properties

Melting Temperature. The polar structure of polyureas results in high melting points that are higher than those of the corresponding polyimides. Aliphatic polyureas melt at lower temperatures than aromatic polyureas. The melting temperature of aliphatic polyureas decreases with increasing number of methylene groups. Thus, nonamethylenediamine gives polyureas with melting temperatures of about 200 – 210 °C that can be injection-molded and extruded [102]. Alkylation or acylation of the nitrogen atoms lowers the melting points [103]. The copolyureas also melt at lower temperatures. For homopolyureas, melting point variations can be seen in Table 3.

The glass transition temperature T_g also depends on structure. Aliphatic polyureas usually have a T_g below 100 °C, whereas the T_g of aromatic polyureas is above 100 °C.

Solubility. Polyureas having polar structures, are difficult to dissolve in organic solvents. Aliphatic polyureas are soluble in phenol, cresols, acetic acid, and similar solvents. Aromatic polyureas are usually soluble only in aprotic dipolar solvents such as DMF, DMA, and NMP [109]. The symmetry or asymmetry of the aromatic monomers influences the solubility of the polyureas. Copolyureas, particularly aliphatic ones, are usually more soluble than polyureas. The solubility of poly(urethaneurea)s can be improved by reaction with trifluoroacetic anhydride to give polymers with =N–$COCF_3$ groups.

Water Absorption and Permeability. The water absorption of polyureas is low and depends on structure. Water absorption is increased by incorporation of heteroatoms, such as oxygen, sulfur, –COOH, or –SO_3H, whereas it decreases with increasing number of carbon atoms. Poly(urethaneurea)s derived from D-glucosamine and diisocyanates have a water absorption of 10 – 24 % [110]. The water permeability of polyurea films is higher than that of polyamide films.

7.2. Chemical Properties

Thermal Stability. Polyureas have a thermal stability higher than that of polyurethanes

Table 3. Melting points of homopolyureas

Main chain	*mp*, °C	Prepared from	Ref.
Aliphatic	180 – 230	diamines and urea	[104]
Aromatic	260 – 320	diamines and carbon dioxide	[105]
Aliphatic/aromatic	200 – 240	aromatic/aliphatic dihalide and alkali metal cyanate	[106]
Naphthalenediyl	350 – 380	diamines and urea	[107]
Heterocyclic	330 – 350	diamines and diisocyanates	[108]

but lower than that of polyamides [111]. The thermal stability of the urea group is a complex issue. Thus, polyhexamethyleneurea ($mp = 300\,°C$) can be heated to 260 °C without decomposition, whereas polydecamethyleneurea ($mp = 230\,°C$) decomposes rapidly at 260 °C in the molten state. The mechanism of this thermal decomposition has been studied by mass spectrometry and involves a hydrogen transfer to give isocyanates and amines [112] (see above).

N,N′-Disubstituted polyureas decompose at higher temperatures than unsubstituted polyureas because of the higher energy required for the C–H hydrogen transfer, which involves two competing decompositions [112]:

This six-centered transition state is indicated by a peak in the MS (mass spectrometry) spectrum that corresponds to methyl isocyanate [112]. The thermal decomposition of polymers containing a carbonyl group flanked by 1,4-piperazinediyl units involves hydrogen transfer from a methylene group to nitrogen [113]:

A method has been reported for the synthesis of isocyanates by thermal decomposition of polyureas that involves this interesting reaction [114].

Thermal stability of polyureas can be improved by copolymerization to give poly(phosphorylurea)s, poly(silylurea)s, poly(amideurea)s, poly(imideurea)s, etc. Thermal stabilities of *N*-substituted polyureas are higher than those of the corresponding unsubstituted polymers.

Hydrolytic Stability. Polyureas have excellent stability to hydrolysis under acidic and alkaline conditions. For example, polynonamethyleneurea fibers are more resistant to acid than nylon 6 or nylon 6,6; resistance to alkalis is higher than that of poly(ethylene terephthalate). In 40 % sulfuric acid or 40 % caustic soda solution at room temperature, these fibers lose less than 10 % of their strength after 10 h [115].

Improved resistance toward acids and bases has been reported for *N*-substituted polyureas prepared from *N,N′*-dialkylhexamethylenediamines and phosgene [116].

Biodegradation. Copolyureas containing amino acids or peptides in their chains are degraded by living organisms. Copolyureas containing dipeptides are degraded twice as fast as than those containing amino acids [117]. Similar polyureas are also degraded by chymotrypsin or subtilisin [118].

8. Uses

The urea linkages in poly(urethaneurea)s or polyureas extended with diamines cause an increase in phase separation compared to polyurethanes extended with diols. This phase separation improves various mechanical properties, such as elongation at break, hysteresis, and stress elongation [119].

8.1. Foams

Polyurethane and poly(urethaneurea) foams are generally divided into flexible, semiflexible, and rigid products, which can be produced by one-shot or by prepolymer methods.

In the one-shot method, the components are mixed directly, generally with simultaneous addition of auxiliaries such as catalysts, reinforcing agents, fillers, foam stabilizers, and flame retardants. These systems are exothermic.

In the prepolymer method, NCO prepolymers can be obtained from di- or polyhydroxy compounds, usually hydroxy-terminated polyethers or polyesters, which react with di- or polyisocyanates in excess. These NCO prepolymers are important compounds, because they can be cured with active hydrogen atoms from diamines, diols, water, etc. Many polyurethane and poly(urethaneurea) elastomers are produced via NCO prepolymer intermediates.

The curing of NCO prepolymers with diols is used in the production of polyurethane elastomers. The same reaction, but with diamines, gives poly(urethaneurea) elastomers. With aliphatic amines (strong nucleophiles), this reaction is too fast to allow satisfactory mixing and a sufficiently long pot life. For this reason, less reactive aromatic diamines are used as chain extenders, in particular sterically hindered diamines or diamines whose nucleophilicity is weakened by electron-withdrawing groups.

Chain extension with diamines has advantages. For example, this curing process occurs rapidly and without additional heating; short production cycles are therefore possible. Usually, the NCO/NH_2 reaction ratio is about 1 : 1. Symmetrical diamines with deactivating substituents are used for elastomer synthesis, and alkyl-substituted toluenediamines, such as diethyltoluenediamine, are usually employed for reactions with NCO prepolymers in the RIM process.

If this reaction is carried out in polar organic solvents, practically any diamine can be used, even especially reactive aliphatic ones such as ethylenediamine.

The NCO/H_2O reaction (chemical blowing process) is a very important process for the production of foams. This chemical blowing process can be supplemented by physical blowing with low-boiling liquids as blowing agents, such as trichlorofluoromethane, which can be used to reduce the foam density further.

Organometallic compounds such as organotin compounds, in combination with tertiary amines, have a synergistic effect in the catalysis of the isocyanate – water reaction (Table 4) [120].

Linear or slightly branched polyols with a relatively high molecular mass (2000 – 8000) yield flexible foams. Combinations of these polyols with low molecular mass glycols or amines as chain extenders afford semiflexible foams. Highly branched polyols with a relatively low molecular mass (< 1000) yield rigid foams.

Polyurea foam materials are also prepared from diisocyanates with different structures by reaction with water. For flexible foams, linear or slightly branched prepolymers are used; more highly branched prepolymers produce rigid polyurea foams.

Flexible foams are prepared from diisocyanates, polyfunctional polyols, blowing agents, catalysts, and surfactants. Although various diisocyanates have been used for flexible foams, toluene-2,4-diisocyanate (TDI) is preferred. Modifiers, fillers, and plasticizers are used to confer special properties. The flexibility of these foams depends on the molecular mass of the polyesters and polyethers used. The ether group

Table 4. Effects of catalysts on relative reactivities of phenyl isocyanate with active hydrogen compounds in dioxane at 70 °C

Catalyst,	Relative reactivity with		
10 mol %	*n*-Butanol	Water	Diphenylurea
None	1.0	1.1	2.2
N-Methylmorpholine	40	25	10
Triethylamine	80	47	4
Tetramethyl-1,3-butanediamine	260	100	12
Triethylenediamine	1.20	380	90
Tributyltin acetate	80	14	8
Dibutyltin diacetate	600	100	12

imparts flexibility, which, in turn, promotes softness, low melting point, low glass transition temperature, and elasticity. Surfactants promote intimate mixing of the components, regulate and control cell size, and impart stability. Many types are used, such as organic nonionic or ionic surfactants and silicones.

The properties of flexible foams also depend on the processing conditions (mixer speed, air-injection rate, etc.). Polyester-based flexible foams have higher tensile strength and elongation-at-break than polyether foams.

Flexible foams are characterized by reversible deformability and open-cell structure that is associated with air permeability. They have many applications, for example, mattress manufacture, automobiles, and aircraft construction.

Semiflexible foams are used almost exclusively as moldings and are 90 % open-celled. They have lower elasticity and good damping properties. In consequence, they are used as protective cushioning for control panels and consoles and for door and pillar paneling.

Rigid foams are prepared similarly to flexible foams but with different starting materials. In rigid foams, groups that restrict chain rotation, particularly aromatic rings, confer stiffness, which increases the melting point and hardness, and reduces elasticity.

Polyether resins used for rigid foams have lower molecular mass (300 – 1000) than those for flexible foams (3000 – 5000). Polyethers with aliphatic/aromatic structure, prepared from aromatic diamines and propylene oxide, contribute to the stiffness of rigid poly(urethaneurea) foams.

The production of rigid poly(urethaneurea) foams from hydroxy-terminated resins and isocyanates requires auxiliaries such as blowing agents, catalysts, cell-size regulators, flame retardants, surfactants, and cross-linking agents. As with flexible foams, the reaction between diisocyanates and water generates CO_2, which serves as blowing agent. A halogenated hydrocarbon, such as trichlorofluoromethane, may also be employed, because this inert liquid with *bp* 23.8 °C is quickly volatilized by heating. The gas bubbles expand the foam and remain in the closed cells of the final product. In addition, CCl_3F has a low thermal conductivity and is nonflammable.

The density of rigid foams depends on the amount of gas trapped in the cells. A commercial rigid foam that contains 3 % solid polymer and 97 % gas has a density of about 16 kg/m^3. These foams are manufactured in such a way as to minimize convection currents [121]. Rigid foams are predominantly of the closed-cell type. For special uses, open-cell types are also produced.

Mechanical properties depend on the composition used in the formulation and the plastic nature of the foam at high temperature. Rigid poly(urethaneurea) foams provide excellent thermal insulation, especially when blown with fluorocarbons; high strength combined with light weight; heat resistance; and adhesion to wood, glass, ceramics, and fibers. The rigid foams can be used between − 200 and + 130 °C, and for short periods they can tolerate + 250 °C. As cross-linked plastics, the rigid foams are largely stable to chemicals, such as dilute acids and alkalis. The chief uses of rigid foams are in the heat and cold insulation field. They are used for insulation of refrigerators, in-

cluding industrial refrigerators, freezers, and hot water accumulators, and as insulation for industrial tanks, containers, etc.

Polyurea foams are prepared by the reaction of diisocyanates and water; the mechanism is similar to that involved in the preparation of poly(urethaneurea) foams. In this reaction, tertiary amines are used as catalysts. Cu(II) and Zn(II) salts and tertiary amines exhibit a synergistic effect in the catalysis of the MDI – water reaction, which gives polyurea foams with satisfactory properties [122]. In these formulations, when *N,N′*-dimethylaminoethanol is used as catalyst, better results are obtained with copper nitrate as cocatalyst than with zinc nitrate. Flexible polyurea foams are used for cushions and in the automotive industry, where they provide light weight, high strength, and ease of fabrication. Rigid polyurea foams are used for refrigerators and in constructions.

8.2. Moldings

The production of polyurethanes, poly(urethaneurea)s, and polyureas by reaction injection molding (RIM) is now a well-established process. It offers several advantages for high-volume production of large parts: low pressure (< 343 kPa), low temperatures (54 – 60 °C) and use of reactive liquid intermediates [123]. Since the urethane polymerization process is highly exothermic, minimal heat input is required to maintain tooling temperature during production. With polyols, isocyanates, and extenders, different polymers can be formulated with a wide range of properties, from a flexible elastomer to a rigid plastic. The final product can be solid, microcellular, or foam-modified with a variety of fillers. Glass fiber reinforced RIM (RRIM) provides dimensional stability and high impact strength [124].

Poly(urethaneurea) and polyurea elastomers represent new classes of commercial RIM elastomers. They are obtained from diisocyanates and macrodiols or macrodiamines with hindered aromatic diamines as extenders. Diethyltoluenediamine (DETDA) is used in large quantities as an extender for these elastomers which have high thermostability [125]. Because of the high rate of urea formation, aliphatic diamine extenders have found limited application in RIM.

Poly(urethaneurea) and polyurea elastomers have many practical applications; the most important is in the automotive industry. To reduce the weight of automobiles, high-modulus RIM and RRIM materials suitable for external body panels have been developed from these elastomers. In addition, these elastomers are corrosion- and impact-resistant.

Because of their mechanical and thermal properties, these rigid foams are especially suitable for structural applications and can compete with wood, glass fiber reinforced plastics, and other materials.

High-modulus poly(urethaneurea) RIM elastomers are prepared from a prepolymer of MDI and diamine, using a system termed Bayflex 110 [126]. Some properties of Bayflex 110 follow:

Density	1042 kg/m^3
Flexural modulus	
at − 30 °C	829 MPa
at 20 °C	359 MPa
at 65 °C	241 MPa
Tear strength	105 kN/m
Tensile strength	26.2 MPa
Elongation	275 %

These RIM elastomers, manufactured by Mobay Chemicals, have superior physical properties and can be released from the mold after 15 s with excellent green strength.

Polyurea RIM elastomers with high modulus can be prepared from a polyamine (Jeffamine D-2000), polyisocyanate, and an amine-terminated chain extender in an Accuratio V-R100 RIM machine, and released after 1 min. The resulting elastomer is cured at 121 °C for 1 h; properties are given below:

Tensile strength	23 – 28 MPa
Elongation	280 – 360 %
Tear strength	65 – 68 kN/m
Flexural modulus	
at 25 °C	148.2 – 148.9 MPa
at − 29 °C	526 – 599 MPa
Heat sag	6.8 – 11.5 mm

The molding behavior of the RIM polyurethane depends on the catalyst [127]. The catalyst used for the isocyanate – water reaction can affect the physical properties of the final product. Because of yellowing under the influ-

ence of UV light, the moldings must be coated with a paint of high opacity, unless they are colored black or dark brown in the solid. In the photodegradation of MDI-based poly(urethaneurea) elastomers, photo-Fries products have been observed by UV and IR spectroscopy [128].

Polyols in polyurethane and poly(urethaneurea) elastomers increase the hygroscopicity and affect the physical properties. These elastomers are less stable at elevated temperature than polyurea elastomers. Polyisocyanates react slowly with polyols, which prevents automation of the process.

Advances in RIM technology include the development of new polyurea systems for the production of automobile body panels. These catalyst-free systems are based on amine-terminated polyesters. In automobile body panels, polyurea RIM materials offer greater impact resistance at equivalent glass-flake reinforcement; improvement in thermal stability for less distortion during paint cure cycles; and lower water absorption for better environmental resistance. These polyureas are usually prepared by the reaction of an amine – MDI-based isocyanate with an amine-terminated polyether (instead of the standard hydroxy-terminated polyether) and an aromatic diamine as chain extender.

Polyurea RIM elastomers present the following advantages:

- The autocatalytic reaction of isocyanate with amine is faster than the isocyanate – water reaction and results in high modulus polymers for automotive applications
- Catalysts are not necessary, and the process can be automated
- Decomposition and yellowing of the final product do not occur
- The higher thermostability extends their practical utility

Table 5 shows the development of RIM technology for polyurethane, poly(urethaneurea), and polyurea [129]. Texaco produces a polyether with amino end groups and a molecular mass of ca. 4000 (Jeffamine), which can be used to replace the polyols in polyurethanes and poly(urethaneurea)s. Mobay Chemicals investigated and established the optimum conditions for poly(urethaneurea) systems (Bayflex 110) and polyurea systems (Bayflex 150). Dow Chemicals investigated Spectrim HT systems; ICI developed the polyurethane Rubicon; and Admiral Equipment investigated machines with a high degree of automation adapted for a very fast RIM process.

The PHD (Polyharnstoff Dispersion) polyols constitute an important class of poly(urethaneurea)s with applications such as RIM elastomers, which were first prepared at Bayer by a polyaddition reaction in situ from diisocyanates and diamines in a polyol medium [130].

8.3. Fibers

Polyureas can be used for fibers because they have good physical and mechanical properties, melting points over 200 °C, low specific gravity, high stability toward acids and alkalis, and excellent dyeability. For example, polynonamethyleneurea has a melting point of 237 °C and a softening point of about 205 – 210 °C, which are suitable properties for fibers.

Polyureas with fiber-forming properties are also obtained by the reaction of $H_2N(CH_2)_nNH_2$ and $O[(CH_2)_4NCO]_2$. For $n = 4$, the resulting polyurea melts at 223 – 225 °C and is suitable for fibers [131].

A copolymer polyester–polycarbonate – polyurea is suitable for spandex fibers with good resistance to environmental degradation [132].

In an interesting continous solventless process, elastomeric filaments and fibers with a poly(urethaneurea) structure have been prepared by spinning in the gas phase from the corresponding monomers [133].

The addition of a polyurea to polyoxymethylene gives heat-stable transparent fibers with good dye affinity [134].

A polyester – cotton blend with improved luster and washfastness was prepared by impregnating the fabric with a diamine and then with a diisocyanate; calendering the fabric formed the polyurea in situ [135].

8.4. Films and Membranes

An interesting application of polyureas is for new nonlinear optical materials prepared as thin films from aromatic polyureas. For example,

Table 5. Development of polyurethane, poly(urethaneurea) and polyurea RIM elastomers

Parameter	Polyurethanes	Poly(urethaneurea)s	Polyureas (1985)	
	(1974 – 1975)	(1980 – 1984)	at 20 °C	at 70 – 75 °C
Productivity, kg/s	2.3 – 3.2	3.2 – 4.5	5.4 – 6.8	10.9 – 13.6
Cream time, s	4 – 8	2.5 – 3	2 – 2.5	1 – 1.5
Total production cycle∗, s	180 – 420	180	60 – 70	60

∗ Rise time.

such thin films were prepared by simultaneous deposition of 4,4′-diaminodiphenylmethane and MDI. Investigations suggest that the poling process of polymerization of oligomers takes place at about 116 °C under a high electric field to give polar urea bonds with a large residual polarization. This polarization determines the pyroelectic and piezoelectric activities after poling treatment [136].

Similar results have been obtained for polyureas prepared from α,α'-dianilino-*p*-xylene and MDI, whose large second-order optical nonlinearity coupled with their unique optical transparency in the UV region make them potentially useful materials for nonlinear optics [137].

Microporous films for artificial leather can be obtained from poly(urethaneurea)s, provided these materials have adequate mechanical properties and good permeability to water [138]. Large quantities of these polymers are used for artificial leather.

Poly(urethaneurea) membranes with high H_2S/CH_4 selectivity have been obtained [139].

Ultrathin polyurea membranes are employed for water desalination by reverse osmosis. The urea group in polyureas is hydrophilic and resistant to chemicals and organic solvents; thus, these polymers are suitable for ultrafiltration applications [140].

Polyurea films are useful as flexible materials impermeable to air and other gases and for construction of inflatable boats, balloons, and similar applications [141].

Polyisocyanates with the general formula $R(CH_2)_y(NCO)_x$, in which R = alkyl, $y = 0$ or 1, and $x = 2 - 4$, react with polyamines; the resulting polyurea films have good adhesion to steel and aluminum and high resistance to chemicals and solvents [142].

Semipermeable membranes with high salt rejection have been prepared from polyureas [143].

The polyurea films produced by an interfacial polymerization reaction between water and a triisocyanate facilitate the formation of stable emulsions [144].

8.5. Coatings

Coating materials can be made from polyureas or poly(urethaneurea)s in solution or emulsion. A new spraying technology has many practical applications; polymers thus applied show excellent adhesion to a variety of substrates, including sand-blasted or primed steel, aluminum, and concrete. The products include two-component sprayed polyurea elastomers, prepared from amine-terminated polyether resins and polyisocyanates. The polyurea spray elastomers systems require no catalyst and have extremely high reactivity and cure [145]. In other applications, aqueous polyurea dispersions can be used for coatings with improved hardness and solvent resistance [146].

8.6. Biomedical Applications

Several polyurea and poly(urethaneurea) materials exhibit blood compatibility and have found applications in medical equipment and artificial organs [147]. The polymer membranes in pneumatic blood pumps [148] should have high tensile strength, low permanent deformation, low hydrolyzability, and high purity.

The hydrolytic stability of poly(urethaneurea)s in extracellular solutions was studied. After 50 d, failure was observed. After 120 d, resistance decreased by 15 – 20 % due to hydrolytic degradation of the polymers. The rate

of hydrolysis was higher in extracellular solutions than in water [149]. Poly(esterurethaneurea)s are not suitable for medical applications because of their hydrolytic instability caused by the ester group.

Cross-linkable polyureas have been prepared for contact lenses [150].

8.7. Other Applications

Polyureas are used as thickeners for lubricating oils; the resulting lubricating greases have long lifetime at high temperatures, high oxidation resistance, good corrosion protection, high structural stability, and good low-temperature properties [151].

Polyureas and poly(urethaneurea)s can be used for the microcapsulation of herbicides, inks, colorants, medicines, and other products [152], [153].

Polyureas with carboxylic or sulfonic groups are good ion exchangers [154].

Polyureas are used for the removal of oils and bitumen from wastewater by filtration [155].

Petroleum production from oil wells is increased by injection into the borehole of a polyamine followed by a polyisocyanate. These react in situ and form polyureas that contribute to the consolidation of the oil sand and prevent clay swelling [156].

Trimellitic anhydride, polyisocyanates, and polyamines give electric insulator compositions for Cu wire with excellent flexibility and resistance to heat, abrasion, solvents, and thermal shock [157].

9. Safety and Environmental Aspects

Due to the wide range of applications of polyureas, copolyureas, and especially poly(urethaneurea)s, millions of people come into contact with them.

Many years' experience in handling the raw and auxiliary materials for these polymers has shown that these products can be handled safely. Air extraction systems must be present at all workplaces where TDI is processed at room temperature or MDI at temperatures above 40 °C. Aminopolyethers are moderately irritating to the eyes and skin; hence, contact with them should be avoided. The same applies to tertiary amines used as catalysts.

Since the carbon dioxide formed in the reaction of water with isocyanates is a natural constituent of air, it presents no problem. The other blowing agents are discharged into the outside air.

Wastes for which no utilization is possible can be disposed of in incineration plants. Granulated RIM wastes can be molded by the flow molding process at high pressure and high temperature to give new moldings. Fine-ground wastes can be used as fillers in production.

The glycolysis of reinforced reaction injection moldings (RRIM) of these polymers with diethylene glycol or dipropylene glycol at high temperatures can be used for the recovery of polyols and aromatic polyamines as suitable products for new RIM [158].

Organic isocyanates can be prepared by thermal decomposition of polyureas at 220 °C [114]. Another route is to utilize the energy by incineration of these polymers, but the calorific yield is small in comparison with other polymers, for example, polyethylene.

1. Introduction

1.1. General Remarks

Research and development in the academic or industrial context makes extensive use of experimentation to gain a better understanding of a process or system under study. The methodology of *Design of Experiments (DoE)* provides proven strategies and methods of experimental design for performing and analyzing test series in a systematic and efficient way. All experimental parameters are varied in an intelligent and balanced fashion so that a maximum of information is gained from the analysis of the experimental results. In most cases, the time and money spent on the experimental investigation will be greatly reduced. In all cases, an optimal ratio between the number of experimental trials and the information content of the results will be achieved.

DoE is a powerful target-oriented tool. If it is properly employed, creative minds with a scientific and technical background will best deploy their resources to reach a well-defined

10.1002/14356007.e08_e01.pub2

goal of their studies. In contrast to what researchers sometimes fear, experimenters will not be hampered in their creativity, but will be empowered for structuring their innovative ideas. Of course, adopting DoE requires discipline from the user, and it has proved very helpful to take the initial steps together with an expert with experience in the field. The rewards of this systematic approach are useful, reliable, and well-documented results in a clear time and cost frame. A comprehensible presentation and documentation of experimental investigations is gratefully acknowledged by colleagues or successors in research and development teams. The application of DoE is particularly essential and indispensable when processes involving many factors or parameters are the subject of empirical investigations of cause – effect relationships.

DoE is a scientific approach to experimentation which incorporates statistical principles. This ensures an objective investigation, so that valid and convincing conclusions can be drawn from an experimental study. In particular, an honest approach to dealing with process and measurement errors is encouraged, since experiments that are repeated under identical conditions will seldom lead to the same results. This may be caused by the measuring equipment, the experimenter, changes in ambient conditions, or the natural variability of the object under study. Note that this inherent experimental error, in general, comprises more than the bare repeatability and reproducibility of a measurement system. DoE provides basic principles to distinguish between experimental error and a real effect caused by consciously changing experimental conditions. This prevents experimenters from drawing erroneous conclusions and, as a consequence, from making wrong decisions.

1.2. Application in Industry

In industry, increasingly harsh market conditions force companies to make every effort to reach and maintain their competitive edge. This applies, in particular, in view of the following goals:

- Quality of products and services in conformance to market requirements
- Low costs to ensure adequate profits
- Short development periods for new or improved products and production processes (time to market)

Quality engineering techniques are powerful elements of modern quality management systems and make it possible to reach these goals. One important challenge in this context is not to ensure quality downstream at the end of the production line, but to ensure product quality by a stable and capable production process which is under control. By this means, ongoing tests and checks to prove that the product conforms to specification requirements are avoided. This can be realized by knowing the important and critical parameters or factors governing the system and through the implementation of intelligent process management strategies.

A methodical approach, sometimes referred to as off-line quality engineering [1, 2], focuses even further upstream. By considering quality-relevant aspects in the early stages of product and process development, quality is ensured preventively in terms of fault prevention [3, 4]. Naturally, there is considerable cost-saving potential in the early stages of product and process design, where manufacturing costs are fixed to a large extent. The losses incurred for each design modification of a product or process gradually increase with time. In addition, design errors with the most serious consequences are known to be committed in these early stages.

As an outstanding quality engineering tool, DoE occupies a key position in this context. The emphasis is on engineering quality into the products and processes. At the same time, DoE opens up great economic potential during the entire development and improvement period. It is well-known that the implementation and use of corresponding methods increases competitiveness [5 – 9]. DoE is applied successfully in all high-technology branches of industry. In the process industry, it makes essential contributions to optimizing a large variety of procedures and covers the entire lifecycle of a product, starting from product design in chemical research (e.g., screening of raw materials, finding the best mixture or formulation, optimizing a chemical reaction), via process development in process engineering (e.g., test novel technological solutions, determine best operating conditions, optimize the performance of processes), up to production

(e.g., start up a plant smoothly, find an operating window which meets customer requirements at low cost, high capacity, and under stable conditions) and application technology (give competent advice concerning the application of the product, customize the properties of products to specific customer needs). In particular, technologies like high-throughput screening or combinatorial synthesis with automated workstations require DoE to employ resources reasonably.

1.3. Historical Sidelights

The foundations of modern statistical experimental design methods were laid in the 1920s by R. A. Fisher [10] in Great Britain and were first used in areas such as agricultural science, biology, and medicine. By the 1950s and 1960s, some of these methods had already spread into chemical research and process development where they were successfully employed [11 – 13]. During this period and later, G. E. P. Box et al. made essential contributions to the advancement and application of this methodology [5, 14 – 18].

In 1960, J. Kiefer and J. Wolfowitz initiated a profound research of the mathematical theory behind optimal designs, and in the early 1970s the first efficient algorithms for so-called D-optimal designs were developed.

Around the same time, G. Taguchi integrated DoE methods into the product and process development of numerous Japanese companies [19]. One of his key ideas is the concept of robust design [1, 2, 4]. It involves designing products and processes with suitable parameters and parameter settings so that their functionality remains as insensitive as possible to unavoidable disturbing influences. Taguchi's ideas were discussed fruitfully in the United States during the 1980s [1, 5, 20, 21] and caused an increasing interest in this subject in Western industries. At the same time, another set of tools, which in general is not suitable for chemical or chemical engineering applications, became popular under the name of D. Shainin [22, 23].

The 1980s also saw the advent and spread of software for DoE. Various powerful software tools have been commercially available for several years now. They essentially support the generation, analysis, and documentation of experimental designs. Experience has shown that such software can be used by experimenters once the basic principles of the methods applied have been learned. A list of software tools is given in Chapter 8.

Despite these stimulating developments, the majority of scientists and engineers in industry and academic research have still not yet used DoE.

1.4. Aim and Scope

The target group of this article consists of scientists and engineers in industry or academia. The intention is

- To give an insight into the basic principles and strategies of experimental design
- To convey an understanding of the important design and analysis methods
- To give an overview of optimization techniques and some advanced methods
- To demonstrate basically the power of proven methods of DoE and to encourage their use in practice

References for further reading and detailed study are given on all subjects. In particular, [16, 24], and [25] may be regarded as standard monographs on DoE in their respective languages.

2. Procedure for Conducting Experimental Investigations: Basic Principles

DoE should become an integral part of the regular working tools of all experimenters. The methods provided by this approach may be used in experimental investigations on a smaller scale as well as in large projects which, depending on their importance and scope, may involve putting together an interdisciplinary team of appropriate size and composition. It proved to be advantageous to also include staff who take care of the equipment or facility on-site. They often bring in aspects and experiences with which the decision-makers involved are largely unfamiliar. Moreover, involving, for instance, laboratory staff in the planning phase of experiments has a positive effect on their motivation. A DoE

Figure 1. Three essential phases characterize the basic structure of a DoE project

project essentially subdivides into three characteristic phases: the design or planning phase, the actual experimental or realization phase, and the analysis or evaluation phase (Fig. 1). It should be stressed that the design phase is decisive because it is this phase that determines the level of information attainable by the analysis of the experimental results. For more information on this subject and on basic principles of DoE, see [26 – 28].

2.1. System Analysis and Clear Definition of Objectives

A system analysis involves collecting all existing information about the system to be examined and describing the current situation. A precise formulation of the problem and a clear definition of the objectives are very important prerequisites for a successful procedure and for attaining useful results from an experimental investigation. Experiments should never be conducted for their own sake but are to provide objective and reliable information, particularly, as a sound basis for decisions to be made. A clear statement of objectives is crucial, since the experimental strategy and hence the design of the experiments is essentially influenced by the goals to be reached (see Section 2.5). This sounds trivial but is frequently not handled carefully enough in practice. The actual planning or even the performance of experimental trials should not start until all of the aforementioned points have been settled satisfactorily.

2.2. Response Variables and Experimental Factors

Each experiment can be regarded as an inquiry addressed to a process or system (see Fig. 2). Naturally, it must be possible to record its answer or result in terms of measurable or quantifiable response variables (dependent variables). Response variables must be selected such that the characterization of the interesting properties of the system is as complete and simple as possible. Let us consider a batch reaction, for instance. In this case it is certainly not only the conversion of starting material that is of interest as a test result; other potential response variables could be the concentration of undesired byproducts or the duration of the reaction (capacity). For some system characteristics, such as foaming during stirring operations or the visual impression of a pigment, there are often no measurable quantities. In these cases, it may be helpful to assess the results by a subjective rating (e.g., 0: no foam or very beautiful pigment, 1: some foam or beautiful pigment, up to about 7: very much foam or very ugly pigment). When the response variables are selected, it is important to ask questions about the reliability of the corresponding values: How much do the results vary if the experimental runs are conducted under conditions that are as identical as possible? Ideally, a detailed analysis of the measurement system is available which, in particular, provides information on repeatability and reproducibility.

Figure 2. Input – output model of a process or system

The results of experimental runs, i.e., the values of response variables, are affected by various factors. In practically all applications there are disturbing environmental factors, which may cause undesired variations in the response variables. Some of them are hard to control or uncontrollable, others simply may not even be known. Examples of such variables are different batches of a starting material, various items of equipment with the same functionality, a change of experimenters, atmospheric conditions, and — last but not least — time-related trends such as warming-up of a machine, fouling of a heat exchanger, clogging of a filter, or drifting of a measuring instrument.

However, besides collecting and discussing the uncontrollable and disturbing variables, it is essential to collect and weigh up those factors or parameters that can be controlled or adjusted (independent variables), such as temperature, pressure, or the amount of catalyst used. The decision as to which of these experimental factors are to be kept constant during a test series and which are to be purposefully and systematically varied must also be carefully weighed up. The entire scientific and technical system know-how available by then from literature and experience, as well as intuition, must decisively influence not only the choice of the factors to be varied (one should focus on the important ones here according to the latest knowledge) but also the determination of the experimental region, i.e., of the specific range over which each factor will be varied (e.g., temperature between 120 and 180 °C and pressure between 1200 and 1800 mbar). A good experimental design will efficiently cover this experimental domain such that the questions related to the objectives may be answered when the experimental results are analyzed.

2.3. Replication, Blocking, and Randomization

To take the effects of disturbing environmental variables into account and decrease their impact to a large extent, the principles of *replication*, *blocking*, and *randomization* are employed. Moreover, by considering these principles, the risk of misleading interpretation of the results is minimized.

Replicates serve to make results more reliable and to obtain information about their variability. A genuine replicate should consider all possible environmental influences leading to variations within the response variables, i.e., the whole experiment with its corresponding factor-level combination should be repeated from the beginning and with some time delay in between. The results of data analyses must always be seen in the light of this inherent experimental error. Hence, replication does not mean, for instance, analyzing a sample of a product several times. This variability of a response variable is solely a measure of the precision of the analytical test procedure (laboratory assistant, measuring instrument).

It is of crucial importance that environmental factors and experimental factors of interest do not vary together such that changes in a response variable cannot be unambiguously attributed to the factors varied. For example, if two catalyst types were to be compared at various reaction temperatures and if two differently sized reactors were available for this purpose, it would be unwise to conduct all experiments with one catalyst in the smaller reactor and all experiments with the other catalyst in the larger reactor. If, in this case, the results differed from each other, it would be impossible to decide whether the catalyst type or the reactor type or both caused the deviations. The objective of blocking is to predetermine relatively similar blocks — in this case, the two reactors — in which test conditions are more homogeneous and which allow a more detailed study of the experimental factors of interest. Regarding the selection of the catalyst type and reaction temperature, the experiments to be conducted in each of the two reactors must be similar in the sense that variations in the values of a response variable can be interpreted correctly.

It is not always possible, however, to clearly identify unwanted influences and to take them into account, as is the case when blocking is used. Yet these side effects can be counterbalanced by a general use of randomization. Here, in contrast to systematically determining *which* experiments are to be conducted, *the order* of the experiments is randomized. In particular, false assignments of time-related trends are avoided. Let us consider a rectifying column, for instance, in which the effects of operating pressure, reflux

ratio, and reboiler duty on the purity of the top product are to be examined. Let us assume that the unit is started up in the morning and that the whole test series could be realized within one day. Now, if one conducted all experiments involving a low reflux ratio before those involving a high reflux ratio, the effect of the reflux ratio could be falsified more or less by the unit's warming up, depending on how strong this influence is (poor design in Fig. 3). Such an uncontrolled mixing of effects is prevented by choosing the order of the experimental runs at random (good design in Fig. 3).

Figure 3. Time-related effects caused, e.g., by instrument drifts may falsify the analysis of the results when factor settings are not changed randomly (poor design). If environmental conditions vary during the course of an experiment, their effect will be damped or averaged out by randomizing the sequence of the experiments (good design)

The decisive reason for employing the principles of replication, blocking, and randomization is therefore to prevent the analysis of systematically varied experimental factors from being unnecessarily contaminated by the influences of unwanted and often hidden factors. While blocking and randomization basically do not involve additional experimental runs, each replicate is a completely new realization of a combination of factor settings. An appropriate relation between the number of experimental runs and the reliability of its results must be established here on an individual basis.

2.4. Interactions

To avoid an overly limited view on the behavior of systems, it is of great importance to know about the joint effects of experimental factors, that is, their *interactions*. Two variables are said to interact if, by changing one, the extent of impact on a third, namely, a response variable, depends on the setting of the other variable. In other words, interaction between two experimental factors measures how much the effect of a factor variation on a response variable depends on the level of the other factor. Interactions are often not heeded in practice, or they are studied at the price of spending large amounts of time and money on the associated experimental investigation. In addition, what interaction actually means is often not clearly understood. In particular, interaction is not to be confused with correlation. Two variables are said to be correlated if an increase of one variable tends to be associated with an increase or decrease of the other. Especially factorial experimental designs (see Chap. 3) allow, among other things, a quantitative determination of interactions between varied experimental factors.

2.5. Different Experimental Strategies

When processes are to be improved or novel technical solutions are to be tested, but also when plants are started up, several factors are often varied, in the hope of meeting with short-term success, by using an unsystematic iterative trial-and-error approach until satisfactory results are eventually produced. The expenditure involved quickly takes on unforeseeable proportions without affording important insights into the cause-and-effect relationships of the system. The result of this procedure is that, in the end, a comprehensible documentation is not available, and objective, reliable reasons for process operations or factor settings are missing. Furthermore, very little is known in most cases about the impact of factor variations. Experimenting in this way might be acceptable for orientation purposes in a kind of pre-experimental phase. However, one should switch to a judicious program as soon as possible.

To study causal relationships systematically, the experimental factors or parameters are usually varied separately and successively, and the values of a response variable (product, process, or quality characteristic), such as the yield of a chemical product, are shown in a diagram (see Fig. 4). This one-factor-at-a-time method (see

Section 2.6), however, provides only few insights into the subject under study because the effect of a particular factor is only known at a single factor-level combination of the other factors. The response variable may have quite another shape if the levels of the remaining factors are set differently. If the experimental factors in their effect on a response variable do not act additively according to the superposition principle, i.e., if the factors influence each other in their effect on the response variable by existing interactions, a misinterpretation of the results is easily possible, particularly when optimum conditions are to be attained.

When statistical experimental design methods are used, all considered factors are varied in a systematic and balanced way so that a maximum of information is gained from the analysis of the corresponding experiments. This may comprise the statistically sound quantitative determination of the effects of factor variations on one or several response variables (see Chap. 3) or a systematic optimization of factor settings (see Chap. 6). Depending on the experimenter's intention, the following questions can be answered:

- What are the most important factors of the system under investigation?
- To what extent and in which direction does a response variable of interest change when an experimental factor is varied?
- To what extent is the size and direction of the effect of a factor variation dependent on the settings of other experimental factors (interactions)?
- With which factor settings does one obtain a desired state of a response variable (maximum, minimum, nominal value)?
- How can this state be made insensitive to disturbing environmental factors or how can an undesired variability of a response variable be reduced (robust design)?

The question of which experimental strategy should be chosen from a comprehensive range of methods will be governed by the objectives to be achieved in each individual case, taking, e.g., system-inherent, financial, and time-related boundary conditions into account. Every project has its peculiarities. Carefully planned experiments cover the experimental region to be investigated as evenly as possible, while ensuring to the largest possible extent that changing values in a response variable can be attributed unambiguously to the right causes. Information of crucial importance is frequently obtained by a simple graphical analysis of the data without having to employ sophisticated statistical analysis methods, such as variance analysis or regression analysis. On the other hand, the best statistical analysis is not capable of retrieving useful information from a badly designed series of experiments. It is therefore decisive to consider basic DoE principles right from the beginning, above all, however, before conducting any experiments.

2.6. Drawback of the One-Factor-at-a-Time Method

A crystallization process is used in the following to illustrate the deficiency of the frequently used one-factor-at-a-time method. Factors influencing this system are, for instance, crystallization conditions such as geometry of the crystallizer, type and speed of the agitator, temperature, residence time, and concentrations of additives like crystallization and filter aids, as well as of two presumed additives A and B. Possible response variables may be bulk density, abrasion, hardness, and pourability of the crystallization product. Let us assume the simple case that the effects of the two experimental factors — additive A and additive B — on the material's bulk density are to be systematically examined with the aim of obtaining a maximum bulk density. As mentioned before, the experimental factors are usually examined and/or optimized separately and successively. In the example considered here, one would therefore begin by keeping factor B constant and varying A over a certain range until A has been optimally adjusted in terms of a maximum bulk density and enter the result in a diagram (see Fig. 4). The optimal value for A would then be selected and kept constant. The same procedure would then be employed for B. The result of this is a presumably optimal setting for A and B, and hasty experimenters would jump to the conclusion that, in this case, after varying A between 15 and 40 g/L and B between 5 and 17.5 g/L, the highest bulk density is obtained by setting A to 33 g/L and B to 8.5 g/L and that its value is approximately 825

Figure 4. The one-factor-at-a-time method can lead to misinterpretations in systems that are subject to interactions

g/L. However, the response surface in Figure 4, which shows the complete relationship between both experimental factors and the response variable, reveals how misleading such a conclusion can be. This drastic misinterpretation is based on the, in this case, false assumption that the effect of varying one factor is independent of the settings of the other factor. For instance, by using the response surface, one can show that the bulk density values take on a decidedly different shape compared to the first diagram when varying A for B = 15 g/L. The following should be noted: If there are interactions between experimental factors, the one-factor-at-a-time method is an unsuitable tool for a systematic analysis of these factors, which holds true in particular when factor settings are to be optimized. If such interactions can definitely be ruled out, it might well be used. In chemistry, however, it is rather the rule that interactions occur.

3. Factorial Designs

3.1. Basic Concepts

The statistical experimental designs most frequently used in practice are the *two-level factorial designs*. These designs are called two-level because there are only two levels of settings, a lower (−) and an upper level (+), for each of the experimental factors. A full two-level factorial design specifies all combinations of the lower and upper levels of the factors as settings of the experimental runs (2^n design, where n denotes the number of factors). Their principle is illustrated by a simple example of a chemical reaction for which the influence of 2 (2^2 design) and 3 (2^3 design) experimental factors on the product yield is to be examined (Sections 3.2 and 3.3). For a growing number of factors, the number of runs of a full factorial design increases exponentially, and it provides much more information than is generally needed. Particularly for $n > 4$, the number of experimental settings can

be reduced by selecting a well-defined subgroup of all 2^n possible settings of the factors without losing important information. This leads to the fractional factorial designs (Section 3.4).

The restriction of initially using just two levels for each experimental factor often causes some uneasiness for experimenters using this method for the first time. But by using two-level factorial designs, a balanced coverage of the interesting experimental region is achieved very economically. Moreover — owing to the special combination of factor levels — it is also possible to gain deeper insights from the associated individual values of the response variables. A decisive advantage of the two-level factorial designs is that they allow the effects of factor variations to be systematically and reliably analyzed and quantified and that they provide information on how these effects depend on the settings of the other experimental factors. These insights are gained by calculating so-called *main effects* and *interaction effects*. In the calculation of these effects, all experimental results can be used and are included to form well-defined differences of corresponding averages (see Figs. 6 and 9), thereby increasing the degree of reliability. The essential results of this effect analysis can be visualized by simple diagrams (see, e.g., Fig. 7).

In a factorial design, not only continuous experimental factors, such as temperature, pressure, and concentration, which can be set to any intermediate value, but also discrete or categorical factors, such as equipment or solvent type, may be involved. If at least one categorical variable with more than two levels is involved or if curvatures in the response variables are expected and to be explored, factorial designs with more than two levels may be used, e.g., 3^n designs, in which all factors are studied at three levels each, or hybrid factorial designs with mixed factor levels like the 2×3^2 design, in which one factor is varied at two levels, and two factors at three levels [24]. However, especially in the case of continuous factors, other so-called response surface designs are more efficient (see Chap. 4). In the following, the expression "factorial designs" always refers to two-level factorial designs.

For the sake of simplicity, replicates are neglected in the following examples, and variability in the process and in measurement are assumed to be very small. Note, however, that being aware of the impact of experimental error on the reliability or significance of calculated effects is an essential principle of DoE and crucial to drawing valid conclusions. Variability within individual runs having the same settings of the experimental factors will propagate and cause variability in each calculated variable, e.g., main effect or interaction effect, deduced from these single results. Experimental designs, particularly the factorial designs, minimize error propagation.

Factorial designs are treated in most textbooks on DoE, e.g., [16, 24, 25, 29, 30].

3.2. The 2^2 Factorial Design

Let us suppose the influence of two factors — catalyst quantity A and temperature B — on yield y of a product in a stirred tank reactor is to be examined. Figure 5 shows the two levels of both factors involved, as well as a tabular and a graphical representation of the associated experimental 2^2 factorial design. The — in this case two — columns which contain the settings of the experimental factors form the so-called design matrix. The resultant values of the response variable y obtained for the settings A−B−, A+B−, A−B+, and A+B+ are referred to as $y_{\mathrm{A-B-}}$, $y_{\mathrm{A+B-}}$, $y_{\mathrm{A-B+}}$, and $y_{\mathrm{A+B+}}$ respectively. They are entered in the column of the response variable and in the corresponding positions of the graph.

Due to the special constellation of the experimental runs, it is possible to see how y changes when factor A is varied at the two levels of B and what happens when factor B is varied at the two levels of A. Figure 5 reveals that, at the lower temperature of 70 °C (B−), an increase of the catalyst quantity from 100 g (A−) to 150 g (A+) increases the response variable yield by 2 %, while at the higher temperature of 90 °C (B+), increasing the catalyst quantity enlarges the value of the response variable by 18 %, i.e.,

Effect of A for B−
$= \mathrm{E}_{\mathrm{B-}}(\mathrm{A})$
$= y_{\mathrm{A+B-}} - y_{\mathrm{A-B-}}$
$= +2\%$
Effect of A for B+
$= \mathrm{E}_{\mathrm{B+}}(\mathrm{A})$
$= y_{\mathrm{A+B+}} - y_{\mathrm{A-B+}}$
$= +18\%$

ID	Factor	Unit	Lower level (-)	Upper level (+)
A	Catalyst	g	100	150
B	Temperature	°C	70	90

No.	A	B	y
1	-	-	60
2	+	-	62
3	-	+	74
4	+	+	92

Figure 5. Example of a 2^2 factorial design, including a graphical and a tabular representation of the experimental settings and results

Accordingly, the individual effects of a temperature increase can be determined for the different catalyst quantities:

Effect of B for A−

$$=\mathrm{E}_{\mathrm{A}-}(\mathrm{B})$$
$$=y_{\mathrm{A-B+}}-y_{\mathrm{A-B-}}$$
$$=+14\%$$

Effect of B for A+

$$=\mathrm{E}_{\mathrm{A}+}(\mathrm{B})$$
$$=y_{\mathrm{A+B+}}-y_{\mathrm{A+B-}}$$
$$=+30\%$$

As mentioned before, key results of a factorial design are obtained by the calculation of main effects and interaction effects (Fig. 6). The main effect of a factor is a measure of the extent to which a response variable changes on average when this factor is varied from its lower to its upper level. To calculate this main effect, all experimental results obtained at the upper (+) and lower (−) level of the factor are averaged, and the result at the lower setting is subsequently subtracted from that at the upper. This leads to the following equations:

Main effect of A

$$=\mathrm{ME}(\mathrm{A})$$
$$=\frac{y_{\mathrm{A+B-}}+y_{\mathrm{A+B+}}}{2}-\frac{y_{\mathrm{A-B-}}+y_{\mathrm{A-B+}}}{2}$$
$$=\frac{(y_{\mathrm{A+B-}}-y_{\mathrm{A-B-}})+(y_{\mathrm{A+B+}}-y_{\mathrm{A-B+}})}{2}$$
$$=\frac{\mathrm{E}_{\mathrm{B-}}(\mathrm{A})+\mathrm{E}_{\mathrm{B+}}(\mathrm{A})}{2}$$
$$=10\%$$

Main effect of B

$$=\mathrm{ME}(\mathrm{B})$$
$$=\frac{y_{\mathrm{A-B+}}+y_{\mathrm{A+B+}}}{2}-\frac{y_{\mathrm{A-B-}}+y_{\mathrm{A+B-}}}{2}$$
$$=\frac{(y_{\mathrm{A-B+}}-y_{\mathrm{A-B-}})+(y_{\mathrm{A+B+}}-y_{\mathrm{A+B-}})}{2}$$
$$=\frac{\mathrm{E}_{\mathrm{A-}}(\mathrm{B})+\mathrm{E}_{\mathrm{A+}}(\mathrm{B})}{2}$$
$$=22\%$$

The expressions preceding the numerical results in the calculations above show that the main effect of a factor can also be calculated from the mean of the individual effects involved. The two calculated results can now be read as follows: When the catalyst quantity A is increased from 100 to 150 g, the yield increases on average by 10 % from $\frac{60+74}{2}=67\%$ to $\frac{62+92}{2}=77\%$. The temperature B has a stronger impact on the response variable yield within the range of 70 – 90 °C. An increase in temperature leads to an average increase in yield of 22 %. The main-effect diagrams in Figure 7 illustrate these relations graphically.

The effect of a factor variation is strongly dependent on the respective setting of the other factor. This was already shown in Figure 5 and is further illustrated by the two interaction diagrams in Figure 7. The four lines in these diagrams correspond to the four edges of the response surface, also shown in Figure 7. This interaction is a typical case of a synergetic interaction. A simultaneous increase of A and B has

a clearly higher impact on the response variable than the additive superposition of the individual effects, $E_{B-}(A)$ and $E_{A-}(B)$, would lead one to expect. If the value of y_{A+B+} were not 92 but 76 %, there would be no interaction between A and B. The effect of a variation of one of the two factors on the response variable would be independent of the adjustment of the other factor. In this case, the two individual effects would be identical for each factor, i.e., $E_{B-}(A) = E_{B+}(A) = +2\,\%$ and $E_{A-}(B) = E_{A+}(B) = +14\,\%$. The corresponding lines in the interaction diagrams would then be parallel. It seems reasonable now to determine a quantitative measure for the interaction of two factors as the difference of these individual effects, i.e.,

Figure 6. Calculation of the two main effects and the interaction effect in a 2^2 factorial design

Interaction effect between A and B

$$
\begin{aligned}
&= \mathrm{IE}\,(\mathrm{AB}) \\
&= \tfrac{1}{2}\,[\mathrm{E}_{B+}\,(\mathrm{A}) - \mathrm{E}_{B-}\,(\mathrm{A})] \\
&= \frac{(y_{A+B+} - y_{A-B+}) - (y_{A+B-} - y_{A-B-})}{2} \\
&= \frac{y_{A+B+} + y_{A-B-}}{2} - \frac{y_{A-B+} + y_{A+B-}}{2} \\
&= \frac{(y_{A+B+} - y_{A+B-}) - (y_{A-B+} - y_{A-B-})}{2} \\
&= \tfrac{1}{2}\,[\mathrm{E}_{A+}\,(\mathrm{B}) - \mathrm{E}_{A-}\,(\mathrm{B})] \\
&= \mathrm{IE}\,(\mathrm{BA}) \\
&= +8\%
\end{aligned}
$$

From these sequences of expressions it can be seen that the interaction between A and B could be equally defined through the difference of the individual effects of A or the individual effects of B, giving the same numerical result each time. Moreover, the expression in the middle shows that the interaction between A and B — as is the case for the main effects — is nothing but the difference of two averages (this is basically the reason why a factor of $\frac{1}{2}$ is introduced in the definition). This corresponds to the difference of the averages of the results located on the diagonals in Figure 6.

The calculation of the two main effects and of the interaction effect is also represented geometrically in Figure 6. The corresponding analysis table contains columns of signs, which allow calculation of these effects. Each effect may be computed as the sum of signed response values divided by half the number of experiments, where the signs are taken from the column of the desired effect. Note that the signs of the interaction column AB can be generated by a row-wise multiplication of the main-effect columns A and B. Today, however, the effects do not need to be computed like this anymore. Specific DoE software tools (see Chap. 8) use methods such as those described in Section 4.4 and yield numerical and graphical results more easily.

A final interpretation of the experiments could read as follows: The catalyst shows a not yet satisfactory activity at the lower temperature (70 °C). An increase of the catalyst quantity from 100 to 150 g gives a slight improvement but does not yet yield satisfactory values. The situation is different at the higher temperature (90 °C), where the catalyst clearly performs better. In addition, an increase in the catalyst quantity at this temperature has a strong impact on yield.

If all experimental factors are continuous, it will be possible and useful to perform experi-

Figure 7. Diagrams of main effects, interactions, and response surfaces illustrate conspicuously important relations governing the system

mental runs at the center point. It is obtained by setting each factor to the midpoint of its factor range, in our example, to 125 g of catalyst and 80 °C. This isolated additional experimental point gives a rough impression of the behavior of response variables inside the experimental region of interest. If the result in the center point does not correspond to the mean of the results obtained in the corner points of the factorial design, then the response surface of the response variable will have a more or less pronounced curvature that depends on the magnitude of this deviation. The graph in Figure 5 shows a result of 70 % at the center point, which is slightly below the 72 % obtained by averaging the four results of the factorial design. Thus, the response surface must be imagined as slightly sagging in its middle. Of course, with this single additional experiment, it is impossible to determine which of the experimental factors is (are) ultimately responsible for the curvature. This question can only be settled by a response surface design (see Chap. 4).

The analysis shown for one response variable is performed for each response variable so that the effects of factor variations on every response variable are finally known.

3.3. The 2^3 Factorial Design

The concepts and notions introduced in the Section 3.2 can be generalized to three or more factors. Let us suppose that, in addition to the example in Section 3.2, not only the effects of temperature and catalyst quantity but also the impact of changing the agitator type on the yield are to be examined. In analogy to Figure 5, the experimental factors with their respective two settings as well as the 2^3 factorial design, which is obtained by realizing all possible combinations of factor settings, are represented in graphical and tabular form in Figure 8.

ID	Factor	Unit	Lower level (-)	Upper level (+)
A	Catalyst	g	100	150
B	Temperature	°C	70	90
C	Agitator type		current	new

No.	A	B	C	y
1	-	-	-	60
2	+	-	-	62
3	-	+	-	74
4	+	+	-	92
5	-	-	+	57
6	+	-	+	59
7	-	+	+	67
8	+	+	+	82

Figure 8. Example of a 2^3 factorial design, including a graphical and a tabular representation of the experimental settings and results. The experimental settings for agitator type "current" correspond to the 2^2 factorial design in Figure 5

By comparing the values at the ends of the various edges of the cube in Figure 8, it is possible to perform a very elementary analysis. For each factor, the effect of its variation can be studied for the four different constellations of the other two factors. For example, the change from the current to the new agitator type does not lead to the presumed improvement in yield. This may be verified by looking at the four edges going from the front face to the back face of the cube. The deterioration is particularly severe at high temperature where the yield decreases from 74 to 67 % (for the lower level of catalyst) and from 92 to 82 % (for the upper level of catalyst).

More detailed information about the specific and joint effects of the factors is obtained by calculation of the main effects and interaction effects introduced in Section 3.2.

The main effect thereby indicates how much a response variable is affected on average by a variation of a factor and is measured as the difference in the average response for the two factor levels. Figure 9 illustrates this for the factors A (catalyst) and B (temperature). The main effect for C (agitator type) is obtained analogously by calculating the difference of the two averages at the back face and the front face of the cube.

The interaction effect of two factors, more precisely, the two-factor interaction was introduced in Section 3.2. Generally, there will be

$$\binom{n}{2} = \frac{n\cdot(n-1)}{2}$$

two-factor interactions, where n denotes the number of factors. For three factors there are

$$\binom{3}{2} = 3$$

two-factor interactions, namely, AB, AC, and BC. The calculation of a two-factor interaction in a 2^3 factorial design will be demonstrated for AB. This interaction is obtained by calculating the two-factor interaction $\mathrm{IE}_{\mathrm{C}-}(\mathrm{AB})$ at the lower level of factor C and the two-factor interaction $\mathrm{IE}_{\mathrm{C}+}(\mathrm{AB})$ at the upper level of factor C, and then by averaging these two values:

$$\begin{aligned}
&\text{Interaction effect between A and B}\\
&= \mathrm{IE}\,(\mathrm{AB})\\
&= \frac{\mathrm{IE}_{\mathrm{C}-}(\mathrm{AB}) + \mathrm{IE}_{\mathrm{C}+}(\mathrm{AB})}{2}\\
&= \frac{\left(\frac{60+92}{2} - \frac{62+74}{2}\right) + \left(\frac{57+82}{2} - \frac{59+67}{2}\right)}{2}\\
&= \frac{60+92+57+82}{4} - \frac{62+74+59+67}{4}\\
&= +7.25\%
\end{aligned}$$

A two-factor interaction in a factorial design with more than two factors is obtained by taking the average of all individual two-factor interactions at the different constellations of the other factors. The calculation of IE(AB) is also illustrated in Figure 9, where it is seen to be the difference of averages between results on two diagonal planes. Due to the inherent symmetry

No.	A	B	C	AB	AC	BC	ABC	Yield
1	-	-	-	+	+	+	-	60
2	+	-	-	-	-	+	+	62

8	+	+	+	+	+	+	+	82

$$IE(AB) = \frac{60+92+57+82}{4} - \frac{62+74+59+67}{4}$$

$$= \frac{1}{4}\,[+60-62-74+92+57-59-67+82]$$

$$= \underline{\underline{+7.25}}$$

Figure 9. Calculation of main effects and interaction effects in a 2^3 factorial design shown for the main effects of A and B and their two-factor interaction AB

of the design, the calculation of the other two-factor interactions, IE(AC) and IE(BC), can be performed in a similar way. This leads to the respective columns of signs within the analysis table in Figure 9 and to the corresponding diagonal planes within the cube.

Now, if the interaction between A and B at the lower level of C differs from their interaction at the upper level of C, there will be a three-factor interaction, which is defined by the difference of these two individual two-factor interactions:

$$\begin{aligned}
&\mathrm{IE}\,(\mathrm{ABC})\\
&=\tfrac{1}{2}\ [\mathrm{IE}_{\mathrm{C}+}\,(\mathrm{AB})-\mathrm{IE}_{\mathrm{C}-}\,(\mathrm{AB})]\\
&=\tfrac{1}{2}\ \left[\left(\tfrac{57+82}{2}-\tfrac{59+67}{2}\right)-\left(\tfrac{60+92}{2}-\tfrac{62+74}{2}\right)\right]\\
&=\tfrac{62+74+57+82}{4}-\tfrac{60+92+59+67}{4}\\
&=-0.75\%
\end{aligned}$$

Note that this result can also be obtained by using the column of signs corresponding to the three-factor interaction ABC in Figure 9. As in the case of two-factor interactions, the signs within this column are obtained by a row-wise multiplication of the signs of the main effect columns A, B, and C. Obviously, the three-factor interaction is also the difference of two averages (as in the case of the two-factor interaction presented in Section 3.2, this is the reason why the factor of $\frac{1}{2}$ is introduced in the definition). They are obtained by averaging the results located at the vertices of the respective two tetrahedra which make up the cube.

The numerical results of all effects obtainable from the 2^3 factorial design are summarized in the following:

ME(A)	=	9.25 %
ME(B)	=	19.25 %
ME(C)	=	− 5.75 %
IE(AB)	=	7.25 %
IE(AC)	=	− 0.75 %
IE(BC)	=	− 2.75 %
IE(ABC)	=	− 0.75 %

Note again that numerical results like these and graphical results like those of Figure 7 are easily obtained by using specific DoE software (see Chap. 8). Diagrams of main effects and interaction effects may also be generated for factorial designs with more than two factors.

Even though three-factor interactions may really exist in some cases, it is seldom that they play an essential role. So, if their absolute value is clearly higher than most of the main effects and two-factor interactions, it seems reasonable to conclude that the experimental error is of a magnitude that does not allow the reliable estimation of most of the effects (perhaps because they are very small) and/or that at least one response value has been corrupted by a gross systematic error.

If, on the whole, systematic errors can be excluded, it is a legitimate practice to neglect higher-order interactions, such as three- and four-factor interactions, because main effects tend to be larger than two-factor interactions, which in turn tend to be larger than three-factor interactions, and so on. Moreover, if no information about the magnitude of the experimental error is available, it will be possible to obtain a rough estimate of this error by using higher-order interactions, like five-, four-, and even three-factor interactions.

3.4. Fractional Factorial Designs

For a growing number n of experimental factors, the number of experimental settings 2^n increases exponentially in a full factorial design. Simultaneously, the proportion of higher-order interactions increases rapidly. For instance, if $n = 5$, there are 5 main effects, 10 two-factor interactions, and 16 interactions of higher order. Obviously, if n is not small, there is some redundancy in a full factorial design, since higher-order interactions are not likely to have appreciable magnitudes. At this point, the following questions arise:

- Is it possible to reduce the amount of experimental effort in a sophisticated way so that the most important information can still be obtained by analysis of the data?
- Is it possible to study more experimental factors instead of higher-order interactions with the same number of experimental settings?

The answer in both cases is "yes". It leads to the 2^{n-k} fractional factorial designs, where 2^{n-k} denotes the number of experimental settings, n the number of experimental factors, and k the number of times by which the number of settings has been halved compared to the corresponding complete 2^n design with the same number of experimental factors ($1/2^k \cdot 2^n = 2^{n-k}$). The application of fractional factorial designs yields a reduction in experimental effort, which is adapted to the complexity of the system under investigation and to the information required.

Once the experimental runs have been performed, fractional factorial designs are analyzed like full factorial designs, except that fewer values are available. As introduced in Sections 3.1, 3.2, and 3.3, effects are obtained by calculating corresponding differences of averages. However, by doing so, one will discover that effects are confounded. *Confounding* is defined as a situation where an effect cannot unambiguously be attributed to a single main effect or interaction.

No.	A	B	C	y
1	-	-	+	57
2	+	-	-	62
3	-	+	-	74
4	+	+	+	82

Figure 10. Example of a 2^{3-1} fractional factorial design. In the top section the experimental settings and results are shown in geometrical and tabular form. In the bottom section the problem of confounding is illustrated: Calculating ME(C) and IE(AB) leads to the same expression, which is actually the sum of both. It is not possible to determine whether the calculated value is caused by the main effect of C, by the interaction effect of A and B, or by both

Let us consider the 2^{3-1} design, in which the effects of three factors are studied with four experimental settings (see Figure 10). This is an example of a half-fraction factorial design (see Figure 11). By calculating the main effect of C [ME(C) on the left-hand side of Fig. 10] the outcome is not the difference between the averages of four (as in the case of the 2^3 design) but the averages of only two results which are calculated. A similar situation occurs when calculating the interaction between A and B [IE(AB) on the right-hand side of Fig. 10]. Moreover, calculating these effects leads to the same expression. It is actually the sum ME(C)+IE(AB) of both effects. It can also be verified that ME(A) is confounded with IE(BC), and ME(B) with IE(AC). This is an example of a so-called resolution III design.

A slightly different situation occurs when considering the 2^{4-1} design (see Fig. 11). Here the main effects are confounded with three-factor interactions, e.g. ME(A) with IE(BCD), and the two-factor interactions are confounded with each other, e.g., IE(AC) with IE(BD). This is an example of a resolution IV design. The 2^{5-1} design also shown in Figure 11 is an example of a very efficient resolution V design.

The *resolution* of a fractional factorial design largely characterizes the information content obtainable by analyzing the results of a fractional factorial design:

- A fractional factorial design of resolution III does not confound main effects with each other but does confound main effects with two-factor interactions.
- A fractional factorial design of resolution IV does not confound main effects with two-

factor interactions but does confound two-factor interactions with other two-factor interactions.

– A fractional factorial design of resolution V does not confound main effects and two-factor interactions with each other but does confound two-factor interactions with three-factor interactions.

The resolution of the most important fractional factorial designs can be seen in Table 1.

Designs of resolution III are used in the early stages of experimental investigations to gain a first insight into the possibilities and behaviors

Table 1. The 2^{n-k} (fractional) factorial designs with a maximum of 32 experimental settings and their resolution. 2^{n-k} denotes the number of experimental settings, n the number of experimental factors, and $1/2^k$ the factor by which the number of settings has been reduced compared to the corresponding full factorial design with the same number of experimental factors.

Resolution	Number of experimental settings			
	4	8	16	32
III	2^{3-1}	$2^{5-2} - 2^{7-4}$	$2^{9-5} - 2^{15-11}$	$2^{17-12} - 2^{31-26}$
IV		2^{4-1}	$2^{6-2} - 2^{8-4}$	$2^{7-2} - 2^{16-11}$
V			2^{5-1}	
VI				2^{6-1}
Full	2^2	2^3	2^4	2^5

of systems. Particularly beneficial are *saturated designs* for $2^n - 1$ factors in which all degrees of freedom of a 2^n design are exploited. The above-mentioned 2^{3-1} design is an example of such a design in which three factors are studied with four experimental settings. It is "generated" by replacing all columns of signs in the analysis table of Figure 6 by experimental factors, i.e., the settings of factor C at the top of Figure 11 are determined by the column of the two-factor interaction AB in the analysis table of Figure 6. A further important example of a saturated design is the 2^{7-4} design, which allows seven factors to be studied with eight experimental settings. It is generated by replacing AB by D, AC by E, BC by F, and ABC by G in the heading of the columns of signs used for the calculation of effects in Figure 9. With resolution III designs special care must be taken when interpreting the analysis results. Calculated main effects may also be two-factor interactions of other factors.

Resolution IV designs are employed to gain unambiguous information about the individual impact of the experimental factors, while unambiguous information about their two-factor interactions is not yet required. Designs of resolution III and IV are mostly used to find out which factors play an important role. This technique of isolating the important factors is sometimes referred to as *screening*.

Using designs of resolution V or higher does not lead to any loss of decisive information, since the main effects and two-factor interactions are only confounded with higher-order interactions, which in most cases can be neglected. Particularly when $n > 4$, experimental settings can be halved to achieve designs of at least resolution V.

Fractional factorial designs support the iterative nature of experimentation. The experimental runs of two or more fractional factorial designs conducted sequentially may be combined to form a larger design with higher resolution. In this way it is possible to resolve ambiguities by the addition of further experimental runs.

Half-fraction designs possess an interesting and useful projection property: the omission of one arbitrary column in the designs always leads to a full factorial design with respect to the remaining columns or factors. So, if a factor proves to have no significant effect on a response variable, the remaining factors can be analyzed as in the full factorial design. For example, the omission of factor B in the 2^{4-1} design of Figure 11 leads to a 2^3 design for the factors A, C, and D. This may be verified by examining the three remaining columns in the table but also by pushing the upper faces of the two cubes into the lower faces.

4. Response Surface Designs

In some situations factorial designs in which all factors are varied by only using two settings are not adequate for describing the behavior of an experimental system, because a more detailed insight is needed to predict its responses or to find optimal factor settings. In this case, it is often necessary to extend factorial designs and to do additional experiments at other points in the experimental domain. To decide which points to use, *response surface designs* are used [14, 31]. These designs are based on mathematical models that describe how responses depend on experimental factors.

4.1. The Idea of Using Basic Empirical Models

A model is a way to describe a part of reality; ideally it is much simpler and more manageable than that which it describes, but it should nevertheless adequately fulfill a predefined modeling purpose. Since a model can only be an approximate description of the original, it is important to be aware of this purpose when constructing models (see Chap. 2 for typical goals in conjunction with DoE). Models used in DoE are polynomials in several variables, in which the y variable is a response, and the x variables are experimental factors. A set of coefficients is used to describe how the y variables depend on the x variables. Often a process or experimental system can only be adequately described by more than one response, in which case there will be one model for each response, and each model will have its own set of coefficients.

Coefficients are estimated from experimental data which are collected in a corresponding experimental design. Estimating model coefficients from experimental data is called model fitting and represents the principle task of statistical analysis to be performed as soon as response values from experiments are available. An equally important task consists of assessing the quality of a fitted model, as an important step towards qualifying it for use in prediction and optimization or whatever other purpose. In fact it is often possible to improve the performance of a model by taking small corrective measures such as those described in Section 5.4.

The important ideas behind empirical modeling are:

- The model must describe the entire behavior of the process or experimental system that is relevant to answering the questions of the experimenter.
- The experimental design is based on the model and determines which information can be extracted from the experimental results. Statistical analysis is only the tool for extracting this information.
- Neglecting experimental design essentially means missing out on finding all the relevant answers. Picking the wrong design also means missing out on relevant answers.
- Enlarging the scope of the questions always means extending the model and adding experiments to the design.

Using models and setting up designs in this fashion requires that one proceed in the systematic way that has been described in Chapter 2. There are several additional aspects that play an important role in modeling:

- Definition of the experimental domain in which the model should be useful for prediction
- Selection of the correct model type
- Choice of the experimental design that corresponds optimally to the experimental domain and to the model type chosen
- Estimation of coefficients by regression analysis
- Qualification and refinement of the model by continued statistical analysis
- Validation of model predictions by confirmatory experiments
- Use of the model for the purpose of finding optimal factor settings

4.2. The Class of Models Used in DoE

The class of models that is normally used in DoE contains only models which are linear with regard to the unknown coefficients. This is why, in order to estimate coefficients, linear regression methods can efficiently be used [32]. Nonlinear or first-principle models, such as mechanical models, reaction-kinetic models, and more general dynamic models are only rarely used directly when designing experiments; they are commonly approximated by simple polynomial models at the cost of restricting the domain of validity of the model. A direct generation of optimal designs for nonlinear models, i.e., models that are nonlinear in the parameters that are to be estimated, is sometimes possible. However, it is particularly important that such models are very accurate, that experimental errors are small and that initial estimates of the parameters are already available. It is this last point that often makes setting up the correct design very difficult [17].

Polynomial models used in DoE are built up as a sum of so-called model terms:

$$y = b_0 + b_A x_A + b_B x_B + b_{AB} x_A x_B + b_{AA} x_A^2 + b_{BB} x_b^2 + \varepsilon$$

This is an example of a quadratic model for two factors A and B, containing a constant term b_0, linear terms $b_A x_A$ and $b_B x_B$, an interaction term $b_{AB} x_A x_B$, quadratic terms $b_{AA} x_A^2$ and $b_{BB} x_B^2$, and an error term ϵ.

The x represent the settings of the factors in the experimental domain. In factorial designs, they are coded as − 1 and + 1. When factors have continuous scales, like temperature or pressure, this coding can be understood as a simple linear transformation of the factor range onto the interval [− 1, + 1]. This transformation is called scaling and centering; the corresponding equation is:

$$x_{\text{centered \& scaled}} = 2\ (x - x_{\text{center}})\ /\ (x_{\max} - x_{\min})\ .$$

Since $x_{\text{center}} = (x_{\max} + x_{\min})/2$, $x_{\max}$ transforms into + 1 and $x_{\min}$ transforms into − 1 (or simply + and − respectively, when using factorial designs). Centering and scaling allows the influences of different factors with different scales to be compared. In the following discussion it is assumed that all factors are either coded or scaled and centered in this fashion.

The b are the coefficients that are estimated by regression after the experiments have been completed. A question that arises is: How do calculated effects in a factorial design as described in Chapter 3 compare to estimated coefficients of linear or interaction terms in a fitted model?

The answer to this question is quite interesting. Estimating coefficients by multiple linear regression and calculating effects for factorial designs as described in Chapter 3 are mathematically equivalent. In fact, coefficients are simply half of the corresponding effects: Calculating a main effect of a factor ME(A) means estimating the difference Δy in the response that has been provoked by changing the factor A from its lower to its upper level. In contrast, the corresponding coefficient, b_A, is the geometrical slope of the curve describing the dependency of y upon x, i.e., $\Delta y/\Delta x$. Since DoE is based on scaled and centered variables, Δx is exactly 2. So b_A can be estimated by ME(A)/2. This is also true for interaction effects: b_{AB} can be estimated by IE(AB)/2. Estimators are often denoted by ˆ, so $\hat{b}_A = \text{IE (AB)}\ /2$. The constant b_0 can be estimated by calculating the mean of all response values.

For the example that was discussed in Section 3.2, the model equation is $y = b_0 + b_A x_A + b_B x_B + b_{AB} x_A x_B$ and the estimated coefficients are:

$$\hat{b}_0 = \tfrac{1}{5}\ (74+92+70+60+62) = 71.6\%$$
$$\hat{b}_A = \text{ME (A)}\ /2 = 5\%$$
$$\hat{b}_b = \text{ME (B)}\ /2 = 11\%$$
$$\hat{b}_{AB} = \text{IE (AB)}\ /2 = 4\%$$

The benefit of using coefficients lies in the greater generality of the response surface models. These allow:

- Prediction of response variables within the experimental region
- Use of quadratic models for modeling maxima and minima
- Use of mixture models for modeling formulations (see Section 7.1)
- Use of dummy variables for modeling categorical factors (see Section 7.2)
- Correcting factor settings when prescribed settings cannot be exactly met in the experiment
- Nonstandard domains for the model (and the design) that are subject to additional constraints

4.3. Standard DoE Models and Corresponding Designs

For standard DoE models the designs can be chosen off the peg. This means that the design structure is predefined and available in the form of a design table (see, e.g., Fig. 11 for half-fraction factorial designs). For nonstandard models an optimal design has to be generated by using a mathematical algorithm (see Section 7.3).

Standard DoE models are

- Linear models (i.e., linear with regard to the factor variables), containing the constant term and linear terms for all factors involved
- Interaction models, which additionally contain interaction terms of the factors involved
- Quadratic models, which, in addition to all interaction terms, contain quadratic terms

Standard models for two and three factors are shown in Table 2, examples of response surfaces are shown in Figure 12.

Figure 12. Examples of response surfaces of standard models for two factors: linear (A), interaction (B), and quadratic (C) models

Table 2. Standard models for two and three factors

	Linear model	Interaction model	Quadratic model
Two factors	$y = b_0 + b_A x_A + b_B x_B$	$\ldots + b_{AB} x_A x_B$	$\ldots + b_{AA} x_A^2 + b_{BB} x_B^2$
Three factors	$y = b_0 + b_A x_A + b_B x_B + b_C x_C$	$\ldots + b_{AB} x_A x_B + b_{AC} x_A x_C + b_{BC} x_B x_C$	$\ldots + b_{AA} x_A^2 + b_{BB} x_B^2 + b_{CC} x_C^2$

Adding isolated interaction terms to linear models, taking away interaction terms from interaction models, taking away square terms from quadratic models, or even adding cubic terms like $b_{AAB} x_A^2 x_B$, $b_{ABC} x_A x_B x_C$, or $b_{AAA} x_A^3$, to quadratic models gives nonstandard models which can also be used for DoE. Nonstandard models are also obtained when mixture components are investigated together with normal factors, or when so-called dummy variables (indicator variables) are used to code categorical factors that have three or more settings.

Optimal designs for standard and nonstandard models are:

- Linear models: resolution III factorial designs or so-called Plackett – Burman designs (which are very similar to factorial designs) if no interactions are present
- Interaction models with only some interaction terms: resolution IV factorial designs or so-called D-optimal designs (see Section 7.3); resolution IV designs are also used for linear models when interactions may be present but are assumed to be unimportant
- Interaction models with all interaction terms: resolution V (or higher) factorial designs or D-optimal designs
- Quadratic models: central composite designs (CCD; see below) or so-called Box – Behnken designs
- All nonstandard models: D-optimal designs (see Section 7.3)

Factorial designs are discussed in detail in Chapter 3. *Central composite designs* (CCD) are extensions of factorial designs, in which so-called star points and additional replicates at the center points are added to allow estimation of quadratic coefficients (see Fig. 13 and Table 3). The number of star points is simply twice the number of factors and, ideally, the number of replicates at the center is roughly equal to the number of factors. The distance α from the center point to the star points should be greater than one, i.e., the star points should be outside the domain defined by the factorial design. A star distance $\alpha = 1$ is sometimes used; then star points lie in the faces of the factorial design. A good alternative to a CCD is the Box – Behnken design, in which no design points leave the factorial domain [14]. Box – Behnken designs do not contain a classical factorial design as a basis.

CCDs are normally used with full factorial designs, and sometimes with resolution V de-

Figure 13. Central composite design for two factors (left) and three factors (right)

signs. Another class of designs, called Hartley designs [33], are similar to CCDs and are based on resolution III factorial designs. When, as is sometimes done in industrial practice, only some quadratic terms are added to an existing interaction model, it is useful to include star points only for those factors for which quadratic terms have been added.

4.4. Using Regression Analysis to Fit Models to Experimental Data

Factorial designs are orthogonal for linear and interaction models which means that coefficients can be estimated independently of each other. This is why calculating effects as described in Chapter 3 is so easy. For more complex models and designs, the analysis will be based on multiple linear regression (MLR) and its variants, such as stepwise regression, variable subset selection (VSS), ridge regression (RR), and partial least squares (PLS) [34]. All of these methods represent ways of fitting the model to the data, in the sense of minimizing the sum of squared distances from measured response values to model values (Fig. 14). They differ in that the minimization procedure is subject to different constraints, and their performance differs only in the case of badly conditioned designs, i.e., when the design is not really adequate for estimating all model coefficients.

If y_i stands for the observed response value at experiment i and $\hat{y}_i$ represents the predicted value at that point, then the least-squares estimates for the coefficients $(b_0, b_A, b_B, b_{AB}, \ldots)$ are those for which $\Sigma(y_i - \hat{y}_i)^2$ is minimized (remember: $\hat{y}_i$ depends on the $\hat{b}$ values).

5. Methods for Assessing, Improving, and Visualizing Models

There are many statistical tools that allow a basic judgement of whether a fitted model is sound. A useful selection of these is:

- The regression measure R^2 to check the quality of fit
- The prediction measure Q^2 to check the potential for prediction and to prevent so-called over-fit, which means that the model is so close to the data that it models experimental errors
- Analysis of variance (ANOVA), to compare the variance explained by the model with variance attributed to experimental errors and to check for significance
- Lack-of-fit test (LoF) to assess the adequacy of the model
- Analysis of the residuals to find structural weaknesses in the model and outliers in the collected data

These methods are used both to qualify models for prediction and optimization purposes and also to find indications of how to improve the models in the sense of increasing their reliability. The different statistical methods are explained and ways to interpret and use them toward model improvement are discussed.

Figure 14. How least-squares regression works: squared distances from the model to the observed values are minimized

Figure 15. From the example in Section 3.2: observed values y_i and predicted values $\hat{y}_i$ from a model with coefficients $\hat{b}_0 = \bar{y} = 71.6$, $\hat{b}_A = 5$, $\hat{b}_B = 11$, $\hat{b}_{AB} = 4$ (see Section 4.2), so that $\hat{y}_i$, $y_i - \hat{y}_i$ and $y_i - \bar{y}$ can be calculated

5.1. R^2 Regression Measure and Q^2 Prediction Measure

The regression measure R^2 is the quotient of squared deviations due to the model, $SS_{reg} = \Sigma(\hat{y}_i - \bar{y})^2$, and the total sum of squared deviations of the measured data about the mean value $\bar{y}$ $SS_{tot} = \Sigma(y_i - \bar{y})^2$, i.e.,

$$R^2 = SS_{reg}/SS_{tot}.$$

If ordinary least squares is used for fitting the model, $R^2 = 1 - SS_{res}/SS_{tot}$, where $SS_{res} = \Sigma(y_i - \hat{y}_i)^2$, because $SS_{res} = SS_{tot} - SS_{reg}$, the sum of squared residuals. An example for the calculation of R^2 is given in Figure 15 and Table 4. R^2 is always between 0 and 1 and should be as close as possible to 1; how close it should be depends upon the context of the application. When a measuring device is calibrated, R^2 should be above 0.99, whereas when the output of a chemical reaction with several influencing factors is examined, R^2 may well be around 0.7 and still belong to a very useful model.

R^2 is a deceptive measure because it is prone to manipulation: by adding terms to a model, it will always be possible to get a value of R^2 that is almost one, without really improving the quality of the model. On the contrary, many models with a very high R^2 tend to "over-fit" the data, i.e., they model the experimental errors. This is a common and unwanted phenomenon because it decreases the prediction strength of a model. Especially when a design is not orthogonal, one should be wary of over-fit.

To counteract overfit and improve the reliability of model predictions it is useful to consider the prediction measure Q^2. The calculation of Q^2 is similar to that of R^2, except that in the second equation, the prediction error sum of squares (PRESS) is used instead of SS_{res}:

$$Q^2 = 1 - PRESS/SS_{tot}$$

Here, $PRESS = \Sigma\left(y_i - \hat{\hat{y}}_i\right)^2$, where $\hat{\hat{y}}_i$ is the prediction for the ith experiment from a model that has been fitted by using all experiments except this ith one. In a sense $y_i - \hat{\hat{y}}_i$ is a fair measure of prediction errors. PRESS is always greater then SS_{res}, and therefore Q^2 is always smaller then R^2. The relationship between Q^2 and R^2 and an example for the calculation of Q^2 are given in Figure 16 and Table 5.

In good models, Q^2 and R^2 lie close together, and Q^2 should at least be greater than 0.5. This may not be the case if the design is saturated or almost saturated, which means that the number of experiments that have been carried out equals or only slightly exceeds the number of terms in

Table 4. Calculation of R^2 for the example above: SS_{res} = 3.2, SS_{reg} = 648, SS_{tot} = 651.2, hence $R^2 = 1 - SS_{res}/SS_{tot}$ = 0.995. This is a very good value for the regression measure R^2.

	A	B	y_i	$\hat{y}_i$	$y_i - \hat{y}_i$	$y_i - \bar{y}$
1	–	–	60	59.6	0.4	– 11.6
2	+	–	62	61.6	0.4	– 9.6
3	–	+	74	73.6	0.4	2.4
4	+	+	92	91.6	0.4	20.4
5	0	0	70	71.6	– 1.6	– 1.6
Squared sum					SS_{res} = 3.2	SS_{tot} = 651.2

Figure 16. How Q^2 relates to R^2: PRESS $\geq SS_{res}$ and $Q^2 \leq R^2$; $\hat{y}_i$ is usually between y_i and $\hat{\hat{y}}_i$

Table 5. Calculation of Q^2 for the example above: PRESS = 260 and $Q^2 = 1 - 260/651.2 = 0.601$. This is quite a reasonable Q^2 value. Hence, there is no indication of over-fit.

	A	B	y_i	$\hat{\hat{y}}_i$	$y_i - \hat{\hat{y}}_i$	$y_i - \bar{y}$
1	–	–	60	52	8	– 11.6
2	+	–	62	54	8	– 9.6
3	–	+	74	66	8	2.4
4	+	+	92	84	8	20.4
5	0	0	70	72	– 2	– 1.6
Squared sum					260	651.2

the model. In this case, Q^2 may underestimate the quality of the model, because leaving out single measurements may destroy the structure of the design.

It is more dangerous, however, to overestimate the quality of a model, which may happen if many experiments are replicated. In these experiments $\hat{\hat{y}}_i$ will be very close to $\hat{y}_i$ because only one of the measurements is left out in the calculation of $\hat{\hat{y}}_i$. This means that PRESS may be unduly close to SS_{res}, and Q^2 unduly close to R^2. Nevertheless, Q^2 is normally quite a useful measure to prevent overfit.

5.2. ANOVA (Analysis of Variance) and Lack-of-Fit Test

Analysis of variance, usually abbreviated as ANOVA, is a general statistical tool which is used to analyze and compare variability in different data sets. It becomes a powerful tool that can be used for significance testing when assumptions about the error structure underlying the data can be made. In the context of DoE, ANOVA can be used to complement regression analysis and to compare the variability caused by the factors with the variability due to experimental error.

Strictly speaking, “analysis of variance” should be referred to as “analysis of sum of squares” or, even more correctly, “analysis of

the sum of squared deviations", because it is actually this sum of squares that is decomposed (Fig. 17).

Figure 17. Decomposition of SS_{tot} into SS_{reg} and SS_{res}

However, the aim of ANOVA is to see to what extent the variability in the measured data is explainable by the model and to judge whether the model is statistically significant. To make this comparison, SS_{reg} and SS_{res} must first be made comparable by considering the degrees of freedom.

Already when R^2 is calculated, it is arguable that the number of terms in the model p and the number of runs in the design N should be considered in the calculation, and that $R^2_{adjusted} = 1 - [(N-1)SS_{res}]/[(N-p)SS_{tot}]$ should be used instead of $R^2 = 1 - SS_{res}/SS_{tot}$. But since $R^2_{adjusted}$ normally lies somewhere between R^2 and Q^2, these two are quite sufficient for a first model assessment. In any case, $N - 1$ is the total number of degrees of freedom (of variation with respect to the mean value), $p - 1$ is the number of degrees of freedom of the model (not counting the constant), and $N - p$ is the so-called residual number of degrees of freedom.

ANOVA compares the model to the residuals and tells us whether the model is statistically significant under the assumption that the residuals can be used to estimate the size of random experimental error. $MS_{reg} = SS_{reg}/(p-1)$ is compared to $MS_{res} = SS_{res}/(N-p)$, also called the mean square error (MSE), by subjecting them to a so-called F-test for significance. If the quotient, $F_{emp} = MS_{reg}/MS_{res}$, is greater than 1, then there is reason to suspect that the model is needed in order to explain the variability in the experimental data. If this has to be proven "beyond a reasonable doubt" (i.e., for statistical significance), F_{emp} must be greater than the theoretical value of $F_{crit}(p-1, N-p, \gamma)$, which is always greater than 1, where γ is the desired level of confidence.

Taking the square root of MS_{res} furnishes a reasonable estimate of the standard deviation of a single measurement, provided $N - p$ is not too small and MS_{res} does not change dramatically when terms with small coefficients are added to or removed from the model. This number is called the residual standard deviation (RSD or SD_{res}).

In the example that has been used $SS_{reg} = 648$, $p - 1 = 3$, hence $MS_{reg} = 216$. $SS_{res} = 3.2$, $n - p = 1$, hence $MS_{res} = 3.2$. F_{emp} can be calculated as $F_{emp} = \frac{MS_{reg}}{MS_{res}}$, but a comparison to F_{crit} (3, 1, 95 %) is not meaningful, because there is just one degree of freedom. Also the estimate $RSD = \sqrt{MS_{res}} = 1.789$ should not be taken too seriously in this example.

The lack-of-fit test addresses the question of whether the model may have missed out on some of the systematic variability in the data. This test can only be performed if some of the experimental runs have been replicated: When replicates are present, SS_{res} can be further decomposed into a pure error part $SS_{p.e.}$ and a remaining lack-of-fit part SS_{lof} (Fig. 18).

Figure 18. Decomposition of SS_{res} into SS_{lof} and $SS_{p.e.}$

The corresponding significance test compares $MS_{lof} = SS_{lof}/(N-p-r)$ to $MS_{p.e.} = SS_{p.e.}/r$, where r is the total number of replicates of experimental runs in the design. (A replicate count does not include the original run: if there are five runs at the center point, then one of these runs is counted as the original and the four others as replicates; hence, $r = 4$; if a design consisting of eight runs is completely replicated, there are eight runs that have each been replicated once, hence $r = 8$.)

As in ANOVA, a quotient $MS_{lof}/MS_{p.e.}$ greater than 1 means that there may be a lack of fit although the evidence is still weak, whereas a quotient greater than $F_{crit}(N-p-r, r, 1-\alpha) > 1$ means a significant lack of fit at the error probability level α.

The lack-of-fit test method can be regarded as a good complement to the Q^2 prediction measure because the former works well when many replicates are involved, while the latter makes sense when there are only few replicates. Of course, the latter situation is more common in DoE.

5.3. Analysis of Observations and Residuals

Ideally, when models are fitted to data, the model describes all of the deterministic part of the measured values and the part due to experimental error is reflected by the residuals. It is a presumption in linear modeling, i.e., when using least squares fitting as a criterion, that the experimental error is

- Identically (i.e., evenly) distributed over all measurements
- Statistically independent of the measured value, the order of the experiments, the preceding measurement, the settings of the factor variables, etc.

To verify this assumption and to detect outliers, a rudimentary examination of residuals should always be performed as a step toward qualifying the model. The most important tests for residual structure are:

- Test for influence of single observations on the model
- Test for normal distribution and test for outliers
- Test for uniform variance
- Test for independency of measurement errors

These tests can be performed formally as described above for ANOVA and lack-of-fit testing. However, formal testing of hypotheses of the type necessary here usually requires a very high number of residual degrees of freedom $N - p$. Since this number is actively and consciously kept low in DoE, these tests do not often yield useful results. This is why it is common practice to plot observations and residuals in different types of graphs in order to detect structural weaknesses and to find hints on what the problem might be and on how to avoid it.

Common plots are:

- Observed values versus predicted values to see whether there are observations that had undue influence on the model
- Ordered residuals in a normal probability plot to detect outliers and indications of a possibly nonnormal distribution of residuals
- Residuals versus predicted values in order to spot inhomogeneities in variance
- Residuals versus different factor variables to detect weaknesses in the model
- Residuals versus run order to check latent influences of time and autocorrelation

There is a further systematic approach to coping with possible inhomogeneities in variance that was proposed by G. E. P. Box and D. R. Cox in 1964 and that can be summarized in the so-called Box – Cox plot: In addition to fitting a model to the response y, they suggest fitting models to the transformed response $(y^{\lambda} - 1)/\lambda$ for different λ and then to choose $\lambda_{\max}$ such that residuals are closest to normally distributed. The Box – Cox plot, displays performance of a transformation against λ. It is a practical way of finding indications of what type of transformation to the response data may be useful.

5.4. Heuristics for Improving Model Performance

An interesting although somewhat dangerous aspect of DoE and statistical analysis is that of "pruning" models. What is meant by this is the following: When a model displays some weaknesses in the analysis phase explained above, there is often the possibility to improve the performance of a model by simple measures that do not require additional experiments:

- Excluding model terms with insignificant coefficients
- Introducing a transformation
- Excluding observations that seem to unduly dominate the model or that lie far away from the model
- Include one or two terms in the model without overstressing the design, i.e., without having to perform further experiments

Of course there are always situations in which a model remains inadequate and further experiments must be performed to reach the objectives. The following is a set of heuristics, which may help to improve a model in one of several possible situations that may arise during the analysis phase:

– R^2 and Q^2 are both small (i.e., there is just bad fit): check for outliers using a normal probability plot; check that the response values correspond to the factor variables; check pure error if experiments have been repeated; check that no important factors and interactions are missing in the model.
– R^2 is high but Q^2 is very low (below 0.4, i.e., tendency for over-fit): remove very small and insignificant terms from the model (they may reduce the predictive power of the model); check for dominating outliers (by comparing observed and predicted values) and try fitting the model without them (remember, however, that for screening designs with few residual degrees of freedom, Q^2 may be low although the model is good).
– There are clear outliers in the normal probability plot: usually these outliers have not had much influence on the model (otherwise they would be seen when comparing observed and predicted values), however, they often lead to low R^2 values; check what happens when they are removed from the model; check the records, repeat the experiment; mistrust predictions of the model in the vicinity of such outliers; consider that the outlier may contain important information (maybe this is a new and better product).
– There is some structure in a plot showing residuals versus a factor variable (Fig. 19): this is a sign that the model is too weak and should be expanded; this can usually not be done without enlarging the design.

Figure 19. Standardized residuals are residuals divided by RSD = SD_{res} (see Section 5.2). When plotted against a factor variable they may give an indication of how a model can be improved

– In rare cases of analysis it may be observed in a plot displaying residuals versus predicted values that residuals are not homogeneous; this may be the case when a response varies over several orders of magnitude and the size of errors is either proportional to the response values or satisfies some other relation. Indications of this can also be seen in the Box – Cox plot if the optimal exponent $\lambda_{\max}$ deviates significantly from unity. A transformation of the response, e.g., taking logarithms or square roots, may be the correct measure.

Sometimes, the measures suggested above do not lead to a stable model; outliers seem to be present in spite of all attempts to improve the situation, there are bends and curves in the normal probability plot, coefficients are not significant but also not negligible, and so on. This is usually an indication that not enough experiments have been done. It is the authors' recommendation in this case to either

– Reduce all "manipulation" to a minimum (eliminate only obvious outliers from the data and very small coefficients from the model), and use the model knowing that it is weak but may still be useful, or to
– Strip the model down to linear, find the optimal conditions and repeat a larger design here.

In any case the heuristics above cannot repair a model that is simply incorrect, and care must be taken not to succumb to the temptation of systematically perfecting such an incorrect model. This is usually not the purpose of modeling.

5.5. Graphical Visualization of Response Surfaces

When statistical tests such as those described above detect no serious flaws in the model, it is useful to plot the model by reducing it to two or three dimensions and by representing it as a contour diagram (see Fig. 20) or a response surface plot (see Fig. 12).

When the model consists of more than two factors, surplus factors are set constant, usually to their optimum level, i.e., where responses are optimal. Setting a factor constant corresponds to slicing through the experimental domain and reducing its dimension by one. An interesting possibility is setting a third factor constant at three levels, and placing the three contours side by side.

Figure 20. Contour plot of yield, showing the dependency on catalyst and temperature (for the data from Fig. 6 and Fig. 15). It can be seen that there is an interaction between the two factors

Visualizing models is particularly interesting when the modeling involves several responses, because contour diagrams can be used to find specification domains for the factors when specification ranges for the response variables have been imposed (e.g., by the customer of the chemical product to be produced; see Fig. 21).

Figure 21. Superimposed contour plot for two responses used for finding specification domains for the two factors x_A and x_B, given the specifications for the responses $Y^{(1)}$ and $Y^{(2)}$

6. Optimization Methods

A major purpose of using response surface modeling techniques is optimization. There are several approaches to optimization depending on the complexity of the situation. Single-response optimizations are easier to handle and are treated in Sections 6.1 and 6.2. Multi-response optimization requires weighting the different responses according to their importance. This can be quite difficult, and the relevant techniques are treated in Section 6.3.

6.1. Basic EVOP Approach Using Factorial Designs

A very basic approach to optimization was proposed in the 1960s by G. E. P. Box and N. R. Draper [15]. It is known as Evolutionary Operation, or EVOP (and has nothing to do with evolution strategy or genetic optimization algorithms). When performing optimization experiments in a running production unit, it is not possible to vary factors over very large domains. Hence, effects will be small and very hard to detect against an underlying natural variability of the response. The idea is to simply repeat a small factorial design for, for instance, two factors, as often as is necessary so that the random noise can be averaged out and the effects become apparent.

The direction of maximal improvement of a response can be deduced from these effects and can subsequently be used to find a new position for a second factorial design. At this new position the second factorial is repeated until significant effects or a satisfactory result is obtained. This procedure can be repeated until a stable optimum is found (Fig. 22).

Figure 22. Example of a moving EVOP design (2^2 factorial design with a center point) that has found a stable optimum on the right

6.2. Model-Based Approach

When it is less difficult to establish the significance of a model, as is usually the case on a laboratory scale or in a pilot plant, the model can directly be used for optimization. Gradients of the polynomial models are calculated from the model coefficients because they point to the directions of maximum change in the responses. These directions are then used in an iterative search for a maximum or minimum, as was proposed by Box and Wilson [18].

For quadratic and interaction models, it makes sense to use conjugate gradients, which correct the direction of maximum change by the curvature of the model function (Fig. 23). In this way the search for an optimum can often be accelerated. When a predicted optimum lies within the experimental domain, it is usually quite a good estimate of the real optimum, particularly when a response surface model has been used. When it is outside of the domain, where, by construction, the model is most probably not adequate in describing the process or system under study, it should be validated in the fashion described in Section 6.4.

Figure 23. How the conjugate gradient compares to the gradient

6.3. Multi-Response Optimization with Desirability Functions

In an industrial environment, it is usually not sufficient to maximize or minimize one response only. A typical goal is to maximize yields, minimize costs, and reach specification intervals or target values for quality characteristics. But how should one proceed when these goals are contradictory? This question arises quite frequently in practice.

For example, yield, cost, and the quality characteristics are used as responses in an experimental design. The design should be chosen to allow adequate models to be fitted to all responses. For each response, a model will be fitted to its corresponding measured data. Now optimization can be started. Before being able to apply any mathematical optimization algorithm, the goal of the optimization has to be translated from a multidimensional target to a simple maximization or minimization problem. This can effectively be done by using desirability functions. A desirability function $d_j(y^{(j)})$ for one response $y^{(j)}$, measures how desirable each value of this response is. A high value of $d_j(y^{(j)})$ indicates a high desirability of $y^{(j)}$. Many types of desirability functions have been proposed in literature (e.g., [35]). Two-sided desirability functions are used if a target value or a value within specification limits is to be reached (Fig. 24, left), whereas one-sided desirability functions are used if the corresponding response is to be maximized (Fig. 24, right) or minimized.

An example of a two-sided desirability function is:

$$d_j\left(y^{(j)}\right) = 0 \text{ for } y^{(j)} > y^{(j)}_{\max} \; or \; y^{(j)} < y^{(j)}_{\min},$$

$$d_j\left(y^{(j)}\right) = \left(y^{(j)} - y^{(j)}_{\min}\right)^s / \left(y^{(j)}_{\text{target}} - y^{(j)}_{\min}\right)^s$$
$$for \; y^{(j)}_{\text{target}} > y^{(j)} > y^{(j)}_{min},$$

$$d_j\left(y^{(j)}\right) = \left(y^{(j)}_{\max} - y^{(j)}\right)^t / \left(y^{(j)}_{\max} - y^{(j)}_{\text{target}}\right)^t$$
$$for \; y^{(j)}_{\max} > y^{(j)} > y^{(j)}_{target}.$$

This function depends on a target value $y^{(j)}_{\text{target}}$, a minimum acceptable value $y^{(j)}_{\min}$, a maximum acceptable value $y^{(j)}_{\max}$, and two exponents $s,t > 0$ (Fig. 24, left). High values of s and t emphasize the importance of reaching the target; smaller values leave more room to move within $y^{(j)}_{\min}$ and $y^{(j)}_{\max}$.

To build one desirability function for all responses, the geometric mean is usually taken:

$$D(y) = \left[d_1\left(y^{(1)}\right) \cdot d_2\left(y^{(2)}\right) \cdot \ldots \cdot d_k\left(y^{(k)}\right)\right]^{1/k}$$

By substituting the y by the predicted values of the model functions, desirability D becomes a function of the factor variables, $D = D(\boldsymbol{x})$. To find the best possible factor settings, this function D should be maximized by using any efficient mathematical optimization procedure.

Figure 24. Two responses with corresponding desirability functions: a two-sided desirability function for $y^{(1)}$ (target value $y^{(1)}_{\text{target}}$ desired) and two different one-sided desirability functions for $y^{(2)}$ (maximization of $y^{(2)}$ desired)

In many typical applications, production cost and yield tend to increase simultaneously, and the optimizer, in trying to raise yield and lower cost, reaches an optimum somewhere within the experimental domain. Then it is essential to have good information about the quality of predictions in the interior of the domain. It may be necessary to fit a quadratic model to obtain such good predictions.

In a similar fashion, quality characteristics are often contradictory, e.g., more textile strength means less skin and body comfort; again, the optimizer will find an optimal compromise, which means suboptimal settings for the individual responses within the experimental domain.

Often, the predicted optimum is at the border of the experimental region. It is in fact quite typical that, in cases where linear or interaction models are used and no compromises as described above are necessary, two or more corners of the experimental domain are found to be locally optimal. From a mathematical point of view this seems to present a problem, but in fact it is a very promising situation for further improvement of the product or the process under study. Although the models were made to work inside the experimental region, they often also give very useful information just outside the experimental domain.

To be able to make a compromise between different y, it is sometimes more practical to use desirability functions d_j that are not exactly 0 for $y^{(\mathrm{j})} > y^{(\mathrm{j})}_{\max}$ or $y^{(\mathrm{j})} < y^{(\mathrm{j})}_{\min}$, but only close to 0. This allows the comparison of factor settings for which desirability would otherwise be zero, because some of the y are outside of specification. In any case, constructing desirability functions is quite a delicate task, and it is useful to play around with the desirability function when looking for an optimum.

When extrapolating outside the domain of x, remember that predictions using the model deteriorate when the experimental region is left. This means that predicted optima outside the region must always be validated by further experiments.

6.4. Validation of Predicted Optima

There are several reasons why predicted optima from empirical models should always be validated by further experiments:

- Errors in observed responses propagate into predictions of the model and hence into the position of the predicted optima
- The model may be insufficient to describe the relevant behavior of the experimental system under study and lead to bad predictions of optima
- The desirability function used in multiresponse optimization may not correctly depict all aspects of the real goal
- Predicted optima may lie outside the initial experimental domain, where the quality of the model is doubtful
- Predicted optima may be unsatisfying in that not all responses lie near the desired values or within specified ranges.

It is possible within the scope of linear modeling to calculate confidence intervals for all responses, and hence to get a good idea of the quality of prediction. This calculation of confidence intervals is only correct for qualified models as explained in Chapter 5.

Confidence intervals of this type must be mistrusted if there is a significant lack of fit or if Q^2

is very low. They should also be mistrusted if residuals of observed responses in the vicinity of the predicted optima are very large.

In this case and when predicted optima are outside the experimental domain, further experiments are inevitable. A good strategy for this is to find a sequence of experimental settings for which the predictions gradually improve (according to the model). This sequence will start within the experimental domain and will typically leave it at some point (see Fig. 25). Experiments in this sequence should be carefully performed and checked against predicted results. This procedure will usually lead to very good results. It should be emphasized, however, that these experiments are purely confirmatory in nature, they may lead to better products and better processes but they will not lead to better (fitted) models.

7. Designs for Special Purposes

The design methods that have been discussed until now cover many situations in which the cause and effect relationship between several factors and one or more responses of an experimental system are investigated. However there are cases where further methods are necessary to solve modeling problems. Four characteristic situations are treated in this chapter:

- Designs for modeling and optimizing mixtures are used in product optimization
- Designs for categorical factors may be used for raw product screening and for implementing blocking (as described in Section 2.3)
- So-called optimal or D-optimal designs which are implemented for advanced modeling when nonstandard models or irregular experimental domains are to be investigated
- Robust design techniques have the aim of not only optimizing response values but also response variability.

Further interesting topics, such as

- Nested designs, where the levels of factor B depend on the setting of factor A [16, 24]
- The field of QSAR (quantitative structure activity relationships), which is becoming more and more interesting in conjunction with the screening of active ingredients in medicines
- The whole field of DoE for nonlinear dynamic models involving differential algebraic equations

and others, cannot be treated here. The advanced reader is invited to research on his own, particularly on the latter two themes, which are still in constant motion (both of them incidently make extensive use of D-optimal designs to be shortly discussed in the following).

7.1. Mixture Designs

All designs described above assume that all factor variables can be set and varied independently of each other in an arbitrary manner. This is the typical situation in process optimizations, where factors are technical parameters such as temperatures, pressures, flow rates, and concentrations. However, when the goal is to model the properties of a mixture in order to find optimal ratios for its components, then this factor independence may no longer be presumed. There are many branches of the chemical industry and rubber industries where mixtures are investigated, and there is a whole range of characteristic problems:

- Optimizing the melting temperature of a metal alloy
- Reducing cost in producing paints while keeping quality at least constant
- Optimizing the taste of a fruit punch or the consistency of a yogurt
- Increasing adhesion of an adhesive
- Finding the right consistency of a rubber mixture for car tires

These are cases where experimental design methods must be modified to cope with the fact that all components of the mixture must add up to unity, i.e., for three components, $x_A + x_B + x_C = 1$. Nevertheless there are useful models and designs for mixtures. They are based on the so-called mixture triangle or the mixture simplex when four or more components are involved (Fig. 26).

All simplices have the following properties, which facilitate analysis and the visualization of results:

- Response plots can be generated based on the mixture triangle (as contour plots).

Figure 25. Predicting optima based on the model for increasing domains: A strategy in optimization consists of predicting a series of optima while slowly increasing the domain. Experiments should be performed at these predicted optima for validation purposes. In this way either a satisfactory optimum is reached or a further design is employed

Figure 26. For three-component mixtures the cube is no longer the appropriate geometrical object for modeling the experimental domain. The equation $x_A + x_B + x_C = 1$ defines a triangle. Unfolding this triangle leads to the mixture triangle for three factors (left).
Mixtures with four components can be modeled by a simplex; setting one of the factors constant again leads to a triangle for the others, e.g., $x_D = 0.5$, i.e., $x_A + x_B + x_C = 0.5$ (right)

- A simplex is very similar to the cube in that its boundaries and also its sections parallel to its boundaries are again simplices in a lower dimension. This allows contour plots to be used in the mixture triangle even in situations where more than four components are involved; just set the surplus factors constant and put the three important ones into the mixture triangle.
- Lower and upper levels of the mixture factors can be visualized geometrically as cutting off parts of the simplex. An active upper level means cutting off a corner, an active lower level means cutting off the base (or side) of a simplex. When upper levels are active, the experimental domain is no longer a regular simplex, but only a subset thereof, a so-called irregular mixture region.

The best experimental designs for regular mixture regions are so-called simplex lattice designs. Simplex lattice designs place experiments at the corners and along edges and axes of a simplex. Depending on the complexity of the model that is to be fitted, different strategies in picking out the points are used. The most typical design for a linear model is the axial simplex design which consists of experiments at the corners, at the centroid (equal amounts of all components) and midpoints of the axes from the corners to the centroid (Fig. 27, Table 6). Details can be found in [36].

Table 6. Design matrix for an axial simplex design for three mixture-components

Run no.	Comp. A	Comp. B	Comp. C
1	1	0	0
2	0	1	0
3	0	0	1
4	0.6666	0.1667	0.1667
5	0.1667	0.6666	0.1667
6	0.1667	0.1667	0.6666
7	0.3333	0.3333	0.3334

Figure 27. Geometrical view of an axial simplex design for three-component mixtures

When investigating mixtures, it is important to keep in mind that, although it is possible to correlate changes in the responses to changes in the factor settings, it is principally impossible to tell which factors have caused these changes in the responses, because whenever one factor has changed, at least one other factor has also changed. So which one should be made responsible? Example 1: A fruit punch containing pineapple, grapefruit, and orange juice seems to become tastier when pineapple juice is added. Example 2: A long drink containing pineapple and orange juice and vodka seems to become less bitter when pineapple juice is added. Is it possible, in the two examples, to attribute the change in taste to the change in the amount of pineapple?

When mixtures are modeled and optimized, it is not always necessary to use simplex designs and corresponding models. There are principally three ways to proceed, only one of which involves using simplex designs:

- Define component ratios as factors and use the classical factorial design or a CCD (instead of ratios, any other transformation leading to independent pseudocomponents can be used).
- Use a simplex design, as described above, or D-optimal design, as described in Section 7.3.
- Identify a filler component, for example, x_C, which does not have an effect on any of the responses, use a factorial design, a CCD, or a D-optimal design for the remaining components (together with the constraint $x_A + x_B \leq 1$, if necessary), and regression analysis for a model in which the filler variable does not appear.

Analyzing mixture designs requires some care, because due to the dependencies amongst the mixture factors the models must be adapted to the situation. H. Scheffé and D. R. Cox were the pioneers who developed ways to use models correctly for the mixture problem. Details cannot be included here. The reader is referred to the literature [25, 36 – 38].

7.2. Designs for Categorical Factors

Not all factors that influence a product or a process can be quantified. Examples of nonquantifiable or so-called categorical (or discrete) factors are:

- The supplier of a raw material, who may influence some of the quality characteristics of an end product
- The date or the time of the year may influence how well a process will perform
- Different persons doing the same experiments
- The type of catalyst or solvent
- Mutants of a strain of bacteria in a fermentation process

All these are possible influencing factors that cannot be quantified in a satisfactory manner. (In the case of investigating solvents it would be a very good idea to consider polarity as a

quantifiable factor instead of just the type of solvent.) Hence, particularly when more than two instances of a categorical variable must be considered, new design techniques are necessary.

Typical questions that arise in conjunction with categorical or discrete factors are:

- How large is the impact of a qualitative factor? Is it significant?
- If so, which instance yields the best results?
- Does the categorical factor interact with other factors? Are there interactions between different categorical factors?
- Is a possible optimum for the other (continuous) factors robust with respect to varying the categorical factor? If so, where does it lie?

If there are just two instances or categories of a qualitative factor, it is easy to encode them as "−" and "+" and to use factorial designs. The categorical or qualitative factor can then be used in calculations like a continuous quantitative factor. Effects and coefficients can be calculated in the usual way, and they measure how large the influence of changing categories is. The same is true for interactions with other factors; they measure how the influence of these factors on the responses changes when changing categories.

Treating categorical factors with three or more instances is much more delicate. Within generalized linear modeling, it is possible to treat factors with three or more instances by increasing the number of dimensions of the problem. Dummy variables are used to differentiate between instances: Let p_1, p_2 be two dummy variables and encode instances i_1, i_2, i_3 in the fashion shown in Table 7.

Table 7. How to encode three instances of a categorical factor by using two dummy variables

Coding for	p_1	p_2
Instance i_1	1	0
Instance i_2	0	1
Instance i_3	− 1	− 1

Geometrically the three instances become three points in the two-dimensional coordinate system of the dummy variables. The coded design with example values for a response y as well as the corresponding geometrical visualization is shown in Figure 28.

p_1	p_2	y
1	0	6
0	1	8
-1	-1	13

Figure 28. Geometrical and tabular representation of the design and the response values

Now the advantage of using dummy variables becomes apparent: Analysis of data can be done using the same regression methods as described in Section 4.4, and the interpretation of results, although being somewhat different, is still relatively straightforward:

The model has the form

$$y = c_0 + c_1 p_1 + c_2 p_2$$

where c_1 and c_2 are coefficients pertaining to the dummy variables p_1 and p_2.

Model predictions for the instances i_1, i_2, i_3 become:

$$\hat{y}(i_1) = c_0 + c_1$$
$$\hat{y}(i_2) = c_0 + c_2$$
$$\hat{y}(i_3) = c_0 - c_1 - c_2$$

So the coefficients c_1, c_2 are actually a measure of the extent to which instances i_1 and i_2 differ from the mean c_0.

By additionally setting $c_3 = -c_1 - c_2$ the same measure has been found for instance i_3.

For the example shown in Figure 28 the coefficients are $c_0 = 9$, $c_1 = -3$, $c_2 = -1$, $c_3 = 4$.

Designs for categorical variables will normally be adapted to the problem at hand and generated by a computer algorithm. In fact optimal designs, as described in Section 7.3, should be used.

It is interesting to note that dummy variables can be used to model interactions: Just use these variables in interaction terms of a model. The coefficients then measure by how much the effect of another factor varies from a given instance to its mean effect taken over all instances (i.e., its

Figure 29. An optimal design with constraints and inclusion of some old experiments

main effect). It would go beyond the scope of this article to go into details about this, in particular about calculation of degrees of freedom. A short digression on dummy variables and their use for modeling blocking can be found in [32].

7.3. Optimal Designs

The usual procedure in planning an experimental design is to identify factors and responses, to determine ranges for the factors, and then to choose a standard design amongst those that have been discussed. This design may be factorial, Plackett – Burman, CCD, Box – Behnken, Simplex, or the like. However, in some situations none of the standard designs are suitable. Such situations typically are:

- Use of nonstandard models
- Use of nonstandard experimental domains (i.e., constraints involving more than one factor)
- Special restrictions on the number of runs or tests that can be performed
- Use of mixture designs when either upper factor levels are active (this means that the regular simplex structure is corrupted) or when normal continuous factors are to be investigated in the same design
- One or more categorical factors with three or more discrete settings are present.

In these cases it is common practice to generate a design by using a mathematical algorithm that maximizes the information that the design will contain. Such designs depend on the model to be used and on the experimental domain to be covered.

Criteria involved in optimizing designs are based on the extended design matrix, usually denoted by $\boldsymbol{X}$, which is built up of the design matrix and extended by a column for each term in the model. The basic idea behind optimal designs is to ensure that there are no correlations between the columns of this $\boldsymbol{X}$ matrix. For if there are correlations here, then the influence of the terms involved cannot be resolved (this situation is similar to that described in Section 7.1 in conjunction with mixture components, which are always correlated).

Working with optimal designs (Fig. 29) involves:

- Defining the experimental domain (including possible constraints)
- Choosing the appropriate model
- Specifying experiments that the experimenter explicitly wants to perform or has already performed
- Selecting the optimization criteria for the design
- Specifying approximately how many experimental runs can be performed.

Typically not just one design is generated, but a whole number of designs of differing size (test or run number). This makes it possible to evaluate designs by comparing the optimality criteria for different designs. Typical criteria are D-optimality, G-optimality, A-optimality, and E-optimality. They are essentially variance-minimizing design criteria in the sense that the variances of model predictions or model coefficients are minimized. The most commonly used criterion is D-optimality, which leads to a maximized determinant of the squared $\boldsymbol{X}$ matrix. For more details, in particular, for further optimality criteria, the reader is referred to special literature on optimal designs [39, 40].

Optimal designs will have a high quality if a sufficient number of experimental runs or tests has been allowed for. They are analyzed by regression analysis like other designs, and the cor-

responding models can be used for prediction and optimization purposes.

7.4. Robust Design as a Tool for Quality Engineering

Sometimes the goal of investigation goes beyond estimating the effects of influencing factors and predicting process behavior or quantifiable product characteristics. A typical application of DoE techniques is toward finding conditions, i.e., factor settings, for which not only quantifiable responses are optimal (usually in a multivariate way as described in Section 6.3) but also the variability of response values is minimal with respect to disturbing or environmental factors that act during production or field use of the product. Typically, these influences can not all be controlled or are too expensive to be controlled even during the experimentation phase.

Doing DoE with the goal of reducing variability is known as robust design. In a robust design, control factors or design factors are varied in a design as described above, typically in a screening design, and experiments are repeated at each trial run so as to estimate the standard deviation (or variance) at each trial. This dispersion measure is employed as a new response value. Statistical analysis and optimization tools such as those described above are then used to quantify and finally to minimize variation, while at the same time improving product characteristics.

Taguchi [1, 19, 20] introduced an additional idea into robust design, namely, the concept of so-called noise factors or environmental factors [1, 11]. These are introduced as perturbing factors in a designed experiment with the idea that they simulate possible external influences which may effect the quality of products after they have left the plant. These factors, which will in fact increase the standard deviation, are varied in a second experimental design which is performed for each of the trial runs in the design for the design factors. To distinguish between the two designs, the design for the environmental factors is sometimes called outer array and that for the design factors is called inner array. The use of outer arrays is recommended, when noise factors can rather cheaply be varied independently of the controlled factors.

Example: During the production of CDs a transparent coating is applied to protect the optical layer. CDs are placed onto a turntable, a droplet of lacquer is applied, and the CD is spun to spread the lacquer. Parameters to be varied are the size of the droplet, the speed and the acceleration of the turntable and the temperature in the room. CDs are to be subjected to different extreme climatic conditions in order to simulate their performance in the field. This is to be done in a climate chamber. Factors to be varied in the corresponding outer array are humidity and temperature in the climate chamber. For the inner array a 2^{4-1} factorial design with 3 realizations at the center point is chosen, for the outer array a simple 2^2 full factorial (Table 8). Results from the four experiments in the outer

Table 8. A design for a quality engineering problem, using a 2^{4-1} factorial with center point as inner array and a 2^2 factorial as an outer array.

Run	Design factors; A, B, C, D				Environmental factors: H, T				Mean	Variance
					H = −	H = −	H = +	H = +		
					T = −	T = +	T = −	T = +		
	A	B	C	D	$y1$	$y2$	$y3$	$y4$	y-mean	y-var
1	−	−	−	−						
2	+	−	−	+						
3	−	+	−	+						
4	+	+	−	−						
5	−	−	+	+						
6	+	−	+	−						
7	−	+	+	−						
8	+	+	+	+						
9	0	0	0	0						
10	0	0	0	0						
11	0	0	0	0						

array are taken together, and the mean and the variance are calculated and subjected to effect calculation or regression analysis.

8. Software

Selected DoE software and suppliers are listed in Table 9.

1. History

Cyclodextrins were first mentioned under the name "cellulosines" by VILLIERS in 1891. The first detailed description of their preparation and isolation from bacterial cultures was made by SCHARDINGER in 1903, therefore cyclodextrins are sometimes referred to as "Schardinger dextrins". In 1935 PRINGSTON discovered the complexing properties of cyclodextrins. Finally, in the 1950s the cyclic structure of these compounds was elucidated by FREUDENBERG and CRAMER. The first industrial production of cyclodextrins started in the 1970s in Hungary and Japan [1].

2. Structure

2.1. Molecular Structure

Cyclodextrins are cyclic oligosaccharides with a defined number of D-glucose monomers in the ring. All glucopyranose units are linked by glycosidic $\alpha(1 \rightarrow 4)$ bonds.

The three most important cyclodextrins (CDs) consist of 6, 7, or 8 glucose units and are named α-cyclodextrin, β-cyclodextrin, and γ-cyclodextrin, respectively. Higher homologues have been described but have gained no industrial significance up to now.

2.2. Secondary Structure

The three-dimensional structure of cyclodextrins resembles a truncated cone with a hydrophobic cavity. All secondary hydroxyl groups at C2 and C3 are directed towards the wider opening of the cavity, whereas the primary hydroxyl groups at C6 are located on the narrow opening. The C-H groups and a ring of glycosidic oxygen bonds are directed inside the cavity

Figure 1. Molecular lipophilicity pattern of β-CD [2]

causing its hydrophobic character. The molecular lipophilicity pattern of β-cyclodextrin is shown in Figure 1.

3. Properties

Physical Properties. Selected physical properties of α-, β- and γ-CD are listed in Table 1.

Cyclodextrins are insoluble in alcohols, ketones, ethers, chlorinated hydrocarbons, and aliphatic and aromatic hydrocarbons.

Chemical Properties [3]. Cyclodextrins are chiral, nonreducing oligosaccharides. Upon oxidation with periodate the glucose rings are cleaved; neither formic acid nor formaldehyde is produced. The only degradation product of all cyclodextrins in acidic solution is glucose. The hydrolysis rate follows the order $\gamma > \beta > \alpha$. Under acidic conditions cyclodextrins are hydrolyzed more slowly than maltooligosaccharides. The glycosidic bond in cyclodextrins is hydrolyzed by α-amylase but not by β-amylase. The rate of enzymatic hydrolysis is fastest with γ-CD, followed by β-CD and α-CD. All cyclodextrins are very stable and highly soluble in alkaline solution (pH > 14). In fact the solubility in water can be highly increased in basic solutions. Under nitrogen atmosphere cyclodextrins are stable up to 250 °C [4].

Substitution of hydrogen of the primary and secondary hydroxyl groups leads to cyclodextrin derivatives. Most reactions are carried out in aqueous solutions (all mentioned in Fig. 4 except acetylations). Other suitable solvents are dimethyl sulfoxide, dimethyl formamide, and pyridine.

4. Production [5]

Cyclodextrins are prepared by enzymatic degradation of starch with cyclodextrin glycosyltransferase (CGTase) at 30 – 90 °C. For industrial production corn and potato starch are most important, but wheat and tapioca starch can also

Table 1. Physical properties of the most important cyclodextrins

be used. Several microorganism are able to produce CGTases, for example *Bacillus macerans*, *Bacillus megaterium*, *Bacillus subtilis*, *Bacillus firmus*, *Bacillus circulans*, *Klebsiella pneumoniae*, or *Klebsiella oxytoca*.

The main steps for the production of cyclodextrins comprise:

- Cultivation of a microorganism which produces the CGTase enzyme
- Separation and purification of the enzyme
- Prehydrolysis of starch with amylases
- Enzymatic conversion of starch with the enzyme
- Inactivation of the enzyme by heat treatment
- Separation of the cyclodextrins from the conversion mixture
- Purification and crystallization from water

4.1. Solvent Process

The aqueous solution of starch is converted to cyclodextrins at a temperature of 30 – 90 °C.

Generally, CGTase enzymes produce all three major types of cyclodextrins, depending on the microbiological source of the enzyme and the conversion conditions. To improve the yield and to alter the ratio of the different cyclodextrins obtained, complexing agents (see Table 2) can be added. Most of the complexing agents form insoluble solid complexes with a certain cyclodextrin. The complex formation shifts the reaction equilibrium towards the desired cyclodextrin and the complex can be separated easily from the liquid conversion mixture. For isolation of the cyclodextrins the complex is dissociated by steam distillation or extraction of the complexing agent with an organic solvent.

The yield can be improved further by utilization of specific enzymes. For example alpha-CGTase produced by *Klebsiella oxytoca* produces predominantly α-cyclodextrin in the initial phase. For large-scale production of γ-cyclodextrin a specific gamma-CGTase was developed.

4.2. Nonsolvent Process

Mainly in Japan a nonsolvent process for the production of cyclodextrins was developed. β-Cyclodextrin produced by this process is approved in Japan as food additive. In this process the reaction mixture consists only of water, starch, and enzyme. The process contains an additional step for the saccharification of the non-converted starch, which is hydrolyzed to maltose and glucose by the action of glucoamylase. The final crystallization of cyclodextrins is difficult in this process.

Only β-cyclodextrin can be produced economically with this technology. Production costs are generally higher than in the solvent process.

5. Inclusion Complexes

The hydrophobic cavity in cyclodextrins is capable to incorporate guest molecules. With this process of molecular encapsulation a cyclodextrin inclusion complex (adduct, clathrate) is formed (see Fig. 3). During the association no covalent or ionic bonds are formed. In solution complex formation and dissociation are in a dynamic equilibrium.

For a complex of 1 : 1 stoichiometry the system can be described as:

$$\mathrm{CD} + \mathrm{G} \underset{\textit{Complex dissociation}}{\overset{\textit{Complex association}}{\rightleftharpoons}} \mathrm{CD} \cdot \mathrm{G}$$

The rate constant k_a for complex association is in the range of $10^0 - 10^8$ mol/s. The complex association therefore is usually a fast process, proceeding within milliseconds. The complex formation is an exothermic reaction ($\Delta H < 0$).

α-Cyclodextrin	1-Decanol	Cyclohexane	 Ethanol
β-Cyclodextrin	Trichloroethylene	 Toluene	
γ-Cyclodextrin	 Bromobenzene	 α-Naphthol	 Cyclohexadec-8-en-1-one

Figure 3. Principles of cyclodextrin inclusion

The complex stability decreases with increasing temperature.

5.1. Preconditions

An important aspects for the formation of cyclodextrin inclusion complexes is the geometry of the guest molecule. The size of a guest molecule must be compatible with the diameter of the cavity, which is dependent on the number of glucose units in the ring. With larger molecules it has to be taken into consideration that only side groups penetrate into the cyclodextrin cavity. In these cases also complexes with higher stoichiometries towards cyclodextrins can be formed. The dependence of the ability to form inclusion complexes with α-, β-, or γ-cyclodextrin on the size of the guest molecules is depicted in Table 3.

The driving forces for complex formation are van der Waals forces, hydrophobic interactions, change in solvation energy for both components and, to a lesser extent, hydrogen bonds. The stability of the complex therefore corresponds to the hydrophobic character of the guest molecule. Very polar or ionic molecules form only weak complexes.

Table 3. Complex formation in dependence on size of the guest molecule

Substance	α-CD	β-CD	γ-CD
Xenon	+	-	-
Chlorine	+	-	-
Bromine	+	+	-
Iodine	+	+	+
Carbon dioxide	+	-	-
Ethylene	+	-	-
Propionic acid	+	-	-
Butyric acid	+	+	-
Cyclohexane	+	+	+
Naphthalene	-	+	+
Anthracene	-	-	+

5.2. Preparation

Most preparations of cyclodextrin complexes are carried out in aqueous systems. Complex formation in the absence of solvent is too slow.

Complexation in Solution. Aqueous solutions of cyclodextrins are agitated with stoichiometric amounts of guest substance at slightly elevated temperatures (40 – 60 °C) for several hours. After the equilibrium is reached water can be removed by freeze drying or spray drying. With many hydrophobic compounds and unmodified cyclodextrins insoluble complexes are obtained which can be isolated by filtration. Drying under vacuum is applied to obtain dry complexes. In some cases the use of polar cosolvents like methanol or ethanol can be of advantage.

Complexation in Suspension. It is not necessary to work with completely dissolved cyclodextrins. Fast complexation can be achieved in stirred aqueous slurries of cyclodextrins and guest substance.

Complexation by Kneading. In the kneading method the water content is further reduced so that the mixture of cyclodextrin, guest, and water forms a paste. To complete complexation this paste is kneaded for 30 – 200 min. Complexation time is usually lower than in the aforementioned methods.

Complexation with Highly Soluble Cyclodextrin Derivatives. Concentrated aqueous solutions of cyclodextrins are stirred with an excess of guest substance. In many cases the formed complexes are very soluble so that uncomplexed material can be removed by filtration. The complex solutions can be used directly or can be spray dried to obtain a water soluble powder.

6. Derivatives

Cyclodextrin derivatives are chemically or enzymatically modified cyclodextrins. As all modifications take place on the hydroxyl groups and all hydroxyl groups are directed towards the outside of the molecule the diameter and the hydrophobicity of the cavity is usually not influenced very much by the modification.

Cyclodextrin derivatives can be divided into the following groups:

$CD–OH \longrightarrow CD–O–R$
R = alkyl, hydroxyalkyl (ether)
R = acyl (ester)
R = glycosyl (branched)
$R = SO_3^-, PO_3^{2-}$
$CD–OH \longrightarrow CD–X$
X = I, Br
$X = NH_2, NHR, NR_2$
X = SH, SR
$CD–CH_2–OH \longrightarrow CD–CO_2H$
Oxidation at C_6

The type of modification can also be classified (see Table 4).

Cyclodextrin derivatives can be characterized by the degree of substitution ($DS = Z/N$). If the substituent can be further substituted, e.g., hydroxyalkylated cyclodextrins, the extend of the substitution can be expressed by the average molar substitution (MS), which indicates the number of substituents per anhydroglucose unit.

The industrially most important cyclodextrin derivatives are the methylated, hydroxypropylated, and branched cyclodextrins (see Fig. 4).

Figure 4. Industrially produced cyclodextrin derivatives

Table 4. Types of modification of cyclodextrins

Type	Z (number of hydroxyl groups/CD which are substituted)	Example
Monosubstituted	$Z = 1$	mono-(6-bromo-6-deoxy)-β-cyclodextrin
Statistically substituted	$1 < Z < 3 \times N*$	methyl-β-cyclodextrin
Persubstituted	$Z = 3 \times N*$	heptakis (2,3,6-tri-O-methyl)-β-cyclodextrin (TRIMEB)
Selectively substituted	$Z = N \times 1{,}2$ or 3	heptakis (2,6-di-O-methyl)-β-cyclodextrin (DIMEB)

$*N$ = number of clucose units (6, 7 or 8)

6.1. Ethers

A comparison of the solubility of different cyclodextrin ethers and natural cyclodextrins in various solvents is given in Table 5.

Methylated cyclodextrins gained interest over the past 20 years. Initial work was focused on specifically substituted heptakis (2,6-di-O-methyl)-β-cyclodextrin and heptakis (2,3,6-tri-O-methyl)-β-cyclodextrin, abbreviated DIMEB and TRIMEB.

Especially DIMEB is very soluble both in cold water (20 – 25 %) and in organic solvents. A major drawback is its poor solubility in hot water and the expensive methods of preparation. The selective substitution in the O2 and O6-positions can only be achieved if the methylation is carried out in the presence of barium salts. Dimethyl sulfate in dimethyl sulfoxide/dimethyl formamide is used as methylating agent.

Highly soluble products (solubility > 50 %) can be obtained economically by statistical substitution with methyl chloride in aqueous sodium hydroxide. A degree of substitution of 1.5 between 2.0 can be obtained in a single-step reaction.

In aqueous solution all methylated cyclodextrins (M-CDs) reduce the surface tension. The viscosity of aqueous M-CD solutions is comparable to that of glucose solutions of the same concentration.

Hydroxyalkylated Cyclodextrins. Among the hydroxyalkylated cyclodextrins only the hydroxypropylated (HP-CD) cyclodextrins are produced commercially [6]. Especially HP-β-CD was developed as a pharmaceutical excipient and for industrial applications. HP-CDs are synthesized by reaction of cyclodextrins with propylene oxide in aqueous solution in the presence of NaOH as catalyst. The desired MS value can be adjusted by the amount of reagent applied and ranges typically between 0.5 and 1.0. The

Table 5. Solubility of cyclodextrin ethers and natural CDs

	α-CD β-CD γ-CD	M-CDs	HP-CDs	CM-CDs
Water	+	++	++	++
Methanol	-	++	++	-

Chloroform	-	++	-	-
Acetone	-	++	-	-
Toluene	-	-	-	-

+ soluble
++ highly soluble

lipophilicity of hydroxyalkylated cyclodextrins is lower than that of methylated cyclodextrins.

Ionic cyclodextrin ethers can be obtained by reaction of cyclodextrins with sodium chloroacetate [*3926-62-3*] under alkaline conditions whereby carboxymethyl cyclodextrins (CM-CDs) are formed. Cationic groups are introduced by using 2,3-epoxypropyltrimethylammonium chloride [*3033-77-0*].

Mixed ethers are known but no commercial advantage of their use could be demonstrated up to now.

Table 6. Pharmaceutical formulations with cyclodextrins

Active ingredient	Cyclodextrin	Application/effect
Hydrocortisone	hydroxypropyl-β-CD	increase in solubility
Piroxicam	β-CD	reduction of side effects
Prostaglandin	α-CD	increase in stability
Cefotiam hexetil	α-CD	enhancement of solubility and dissolution rate
Nitroglycerin	β-CD	stabilization
Itraconazol	hydroxypropyl-β-CD	increase in solubility
Chloramphenicol	methyl-β-CD	increase in solubility

6.2. Esters

Partially acetylated cyclodextrins (A-CD) can be produced by reacting a slurry of cyclodextrin in acetic acid with acetic anhydride under sodium acetate catalysis [7]. These esters are very soluble in water (> 30 %) if the DS is in the range of 0.7 – 1.5 and the substitution is random.

With an excess of acetic anhydride fully substituted (DS = 3) products are obtained. These persubstituted cyclodextrins are soluble in polar organic solvents but insoluble in water.

The selectively substituted heptakis (3-acetyl-2,6-di-O-alkyl)-β-cyclodextrins gained some relevance as stationary phase for gas chromatography.

6.3. Other Derivatives

Branched cyclodextrins can be classified in two categories. In *homogeneously branched cyclodextrins* the substituents consists of glucose (G_1) or its oligomers such as maltose (G_2). In *hetero-branched cyclodextrins* the attached groups are other carbohydrates such as galactose.

For the commercial production of G_1-β-cyclodextrin or G_2-β-cyclodextrin highly branched starch is reacted with CGTases to produce a mixture of branched and natural cyclodextrins followed by separation via column chromatography. The $\alpha(1 \rightarrow 6)$ linkage can also be formed by the reaction of excess maltose with β-cyclodextrin in the presence of debranching enzymes like pullulanase.

The solubility of branched cyclodextrins in water is much higher than that of the parent cyclodextrins. Mixtures of branched cyclodextrins are produced and sold in Japan mainly for food applications.

7. Uses

Through the complexation with cyclodextrins the physical properties of the complexed molecules can be changed. The effects of cyclodextrins on guest substances may be summarized as follows:

- Stabilization against light, oxidation, and thermal decomposition
- Solubilization in water
- Controlled release
- Reduction of volatility
- Odor reduction
- Increase in bioavailability

Table 7. Producers and trade names of cyclodextrins

Company	Country	Products	Tradename
Cerestar	USA	β-CD, HP-β-CD , A-CD	Cavitron
Wacker Biochem	USA,	α-CD, β-CD, γ-CD	CAVAMAX
	DE	M-CDs, HP-CDs, A-CDs	CAVASOL

			Advasep

Table 8. Toxicological data of the cyclodextrins

	α-Cyclodextrin	β-Cyclodextrin	γ-Cyclodextrin
Acute toxicology:			
LD_{50} oral, rat	$>$ 10 000 mg/kg	$>$ 12 000 mg/kg	$\gg$ 8000 mg/kg
LD_{50} oral, mouse	$\gg$ 10 000 mg/kg	$>$ 3000 mg/kg	$\gg$ 15 000 mg/kg
LD_{50} i.v., rat	500 – 750 mg/kg	453 – 788 mg/kg	$\approx$ 4000 mg/kg
Subchronic toxicology:			
90 days, oral, rat (NOAEL)[a]	20 % in daily diet	570 mg kg^{-1} d^{-1}	20 % in daily diet
ADI for humans	not allocated (under work)[b]	5 mg kg^{-1} d^{-1}[c]	not specified[d]
Biodegradability (Zahn–Wellens test)	90 % mineralization within 4 days	90 % mineralization within 4 days	90 % mineralization within 4 days

[a] NOAEL = no observable adverse effect level. [b] Submitted to JECFA for evaluation 2001. [c] JECFA decision 1995, published in WHO Food Additive Series 35, 1996. [d] Not specified = JECFA decision 1998: can be used in food up to all quantities technically necessary, published in WHO Food Additive Series 42, 1999.

Pharmaceuticals. Cyclodextrins are useful as excipients in pharmaceutical formulations (see Table 6).

Cosmetics. γ-CD can be applied for odor reduction in self-tanning creams. Retinol, stabilized by γ-CD, is used in anti-wrinkling formulations [8]. An organic peroxide complexed with β-CD is found in tooth pastes [9]. In aqueous skin tonics cyclodextrins are utilized to remove fatty substances from the skin. Perfume oils can be solubilized by HP-β-CD in toiletries [10].

Household. β-CD is used to encapsulate fragrance components in laundry dryer sheets to reduce their volatility [11]. In odor absorbing sprays cyclodextrin derivatives are used to solubilize perfumes and to reduce bad odor [12].

Foods. β-CD is used to remove cholesterol from fatty substances of animal origin like butter or cream [13]. Cyclodextrins can also be utilized in food as carrier for flavors, which can be protected and delivered by molecular encapsulation [14]. It is possible to modify the taste and reduce unpleasant tastes or odors of food with cyclodextrins. Polyunsaturated fatty acids can be stabilized against oxidation by cyclodextrins [15], [16]. In Japan food preservatives like hinokitiol are used as β-CD complex in packaging materials.

Paints and Coatings. Cyclodextrin derivatives are used in the reversible depression of viscosity of associative thickeners [17]. In wood preservation formulations CD derivatives solubilize organic active ingredients like fungicides or insecticides [18].

Chemical Industry. Cyclodextrin derivatives may be applied as phase transfer catalysts for hydrophobic monomers in the synthesis of polymers [19], [20]. In fermentation processes cyclodextrins can be used to "hide" products that are toxic for microorganisms and, thereby enhance the yield.

8. Economic Aspects

Table 7 gives a list of producers and trade names of the different cyclodextrins and their derivatives.

9. Toxicology [21]

Toxicological data of the cyclodextrins are listed in Table 8.

1. Introduction

1.1. Definition of Intermetallics

Intermetallics is the short and summarizing designation for intermetallic compounds and phases, which result from the combination of various metals and which form a tremendously numerous and manifold class of materials. According to the simple definition in [1] intermetallics are compounds of metals whose crystal structures differ from those of the constituent metals, and intermetallic phases and ordered alloys are thus included. During the last 20 years intermetallic compounds (IMCs) have aroused enormous and still-increasing interest in materials science and technology with respect to applications at high temperatures. Various new struc-

© 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.e14_e01.pub2

tural materials are being developed around the world, in particular in the United States, Japan, and Germany. Besides intermetallics with outstanding high-temperature performance, intermetallics with other outstanding physical properties led to the development of new functional materials much earlier.

The results of the numerous and manifold research and development activities on intermetallics have been published in the respective conference proceedings volumes and review monographs [2 – 8] in addition to scientific journals and research reports.

The present overview, which is an updated summary of a previous report [2], briefly describes the various intermetallics which have already been selected for materials developments or which have been and still are regarded as promising for materials developments.

1.2. Historical Remarks

Intermetallics have been exploited since the beginning of metallurgy, as is exemplified in Table 1. The early intermetallics resulted from alloy systems with low melting temperatures, and the applications relied on the outstanding hardness and wear resistance of intermetallics together with their metallic properties. Because of the metallic behavior of intermetallics, they could be polished, and thus the decorative aspect was also important for many applications. Examples are the bronze coatings in ancient Egypt and the mirrors used by the ancient Chinese, Etruscans, and Romans. Some intermetallics show beautiful colors, e.g. the violet Cu_2Sb ("Regulus of Venus").

Intermetallics became a subject of scientific research with the development of physical metallurgy. Intensive and broad-scale work on intermetallics was initiated by Tammann in Göttingen, Germany, and Kurnakov in St. Petersburg, Russia, around 1900. Work on intermetallics during the first decades of the 1900s already included studies of phase stabilities, phase equilibria, and phase reactions in order to establish phase diagrams, and investigations of chemical, electrochemical properties, and physical properties including magnetism, superconductivity, and mechanical properties. It was recognized that the outstanding hardness of intermetallics is accompanied by an unusual brittleness, and the reasons for this were sought.

In the 1900s intermetallics were used primarily as functional materials. The first industrial applications relied on the special magnetic behavior of certain compounds, and materials developments led, e.g., to Sendust which shows outstanding magnetic properties and wear resistance and is widely used for magnetic heads in tape recorders. In the second half of the twentieth century another important application resulted from the development of new superconducting materials on the basis of the A15 compounds, which are used for superconducting magnets. A third group of functional materials — the shape-memory alloys — make use of a martensitic phase transformation and have found manifold applications since ca. 1970.

An important group of functional materials are the III/V compounds such as InSb, InAs, and GaAs, which have found applications in electronics and thermoelectric power generation. The constituent elements of these compounds represent the transition from metals to metalloids and nonmetals, and the resulting compounds are semiconductors. Hence these intermetallic semiconductors lie outside the field of true intermetallics with metallic behavior.

Intermetallics were not used as structural materials in the past because of their brittleness. The only noteworthy exception is the continuing use of amalgams as dental restoratives. However, various intermetallics have been successfully used as strengthening second phases in conventional alloys for structural applications at high temperatures. Thus it became clear that intermetallics are promising as structural materials for high temperatures because of their high hardness and stability, and numerous investigations began around 1950 with the aim of clarifying the potential of intermetallics for structural applications. Various promising candidates were identified, but the respective materials developments were hampered by unsolved brittleness problems, and these various activities slowly died out in the 1960s.

One offspring of these activities was the development of the electric heating elements based on $MoSi_2$, which rely on the advantageous chemical behavior of this compound, that is, its high oxidation resistance at high temperatures. In the course of superalloy research, sur-

Table 1. Some applications of intermetallics in past and present times [2]

Since ca.	Material or process	Phase	Application
2500 B.C.	cementation	Cu_3As	coating of bronze tools, etc. (Egypt, Anatolia, Britain)
100 B.C.	yellow brass	CuZn	coins, ornamental parts (Rome)
0	high-tin bronze	$Cu_{31}Sn_8$	mirror (China)
600	amalgam	$Ag_2Hg_3 + Sn_6Hg$	dental restorative (China)
1500	amalgam	Cu_4Hg_3	dental restorative (Germany)
1505	amalgam	Sn_8Hg	mirror surface (Venice)
1540	type metal	SbSn	printing
1910	Acutal	$(Cu,Mn)_3Al$	fruit knife (Germany)
1921	Permalloy	Ni_3Fe	high-permeability magnetic alloy
1926	Permendur	FeCo(– 2V)	high permeability magnetic alloy
1931	AlNiCo	NiAl – Fe – Co	permanent magnet material
1935	Sendust	$Fe_3(Si,Al)$	magnetic head material
1938	Cu – Zn – Al, Cu – Al – Ni	CuZn – Al, $(Cu,Ni)_3Al$	shape memory alloys
1950	pack aluminide coating	NiAl, CoAl	surface coating for protection from environment
1956	Kanthal Super, Mosilit	$MoSi_2$	electric heating elements
1961	A15 compound	Nb_3Sn	superconductors
1962	Nitinol	NiTi	shape-memory alloy
1967	Co – Sm magnets	Co_5Sm	permanent magnets

face coatings that protect the coated materials against high-temperature corrosion and which are based primarily on such intermetallics as NiAl and CoAl were developed.

The above-mentioned molybdenum disilicide is a borderline case of an intermetallic, since silicon is not a metal, but a semiconductor. It is known that the combination of silicon with metals gives rise to compounds with metallic properties like $MoSi_2$, as well as compounds with semiconductor properties, that is, silicides represent the transition from intermetallics to compounds of metals and nonmetals. Nevertheless, silicides are traditionally included in the field of intermetallics because of their many similarities with metals.

The first intensive and successful developments of structural materials were based on the titanium aluminides Ti_3Al and TiAl and began in the early 1970s, although the potential of these compounds for high-temperature applications had already been recognized in the 1950s.

Other successful structural materials were based on the nickel aluminide Ni_3Al, which is the strengthening second phase in the superalloys and was also a candidate compound in the 1950s. This development was given impetus by the discovery of the "ductilizing" effect of small additions of boron, which led to major research programs on intermetallics and excited the general and still-increasing interest in intermetallics. These successful developments initiated work on other less common compounds with the aim of lower density and/or higher application temperatures.

2. General Considerations

2.1. Crystal Structure and Compound Stability

Intermetallics form because the strength of bonding between unlike atoms is larger than that between the respective like atoms. Accordingly, intermetallics have particular crystal structures with ordered atom distributions in which atoms are preferentially surrounded by unlike atoms. The known intermetallic compounds are listed with their crystal structures in [9].

The crystal structure of an intermetallic is determined by the strength and character of bonding in the crystal, which depends on the particular electron configuration. The relation between structure type and atomic properties of the constituent atoms, however, is not a simple one, and therefore various criteria have been used for correlating structure type and compound type. The grouping of intermetallics according to simple criteria is not unambiguous, and it cannot be expected that all intermetallics will show metallic bonding like the constituent metals. In the following a brief survey of three important and rather different groups of intermetallics is given to illustrate this.

The *Zintl phases* are formed by metals on the left-hand side and on the right-hand side of

the periodic table of elements and are characterized by completely filled electron orbitals, in particular, by a full octet shell in the normal case. Thus they may be regarded as valence compounds which satisfy the familiar chemical valency rules. The Zintl phases have crystal structures which are characteristic for typical salts, for example, NaTl with cubic B32 structure (*Strukturbericht* designations are used here and in the following for the crystal structures) and Mg_2Si with cubic C1 structure, and therefore ionic bonding is expected. However, all types of bonding — ionic, metallic, and covalent — and mixtures thereof have been found, depending on the particular electron distribution. Hence the Zintl phases may also be regarded as electron compounds whose electron band-structure energy is a large fraction of the total energy and the crystal structure types of which are related to particular valence electron concentrations (average number of valence electrons per atom).

The best-known electron compounds are the *Hume – Rothery phases*, which have the cubic B2 structure (e.g., β-brass at high temperatures and the transition metal aluminides FeAl, NiAl, and CoAl), the complex cubic A13 structure (β-Mn type; e.g., Zn_3Co, Cu_5Si), or the close-packed hexagonal A3 structure (e.g.; Cu_3Ga, Ag_3Al) for the valence electron concentration VEC = 3/2; the complex cubic $D8_2$ structure (γ-brass type) for VEC = 21/13 (e.g.; Cu_5Zn_8, Fe_5Zn_2); and the A3 structure again for VEC = 7/4 (e.g., $CuZn_3$, Ag_5Al_3). The bonding in such intermetallics is not purely metallic, in spite of the metal-like band structure. For example, the bonding in the above-mentioned NiAl is essentially covalent with some metallic character and no ionic component. Recent ab initio calculations showed that, strictly speaking, the B2 aluminides are not Hume – Rothery electron compounds. This means that the Hume – Rothery rules, which relate crystal structure to valence electron concentration, represent a very simplified picture of the bonding situation. Nevertheless, such rules are useful since they describe reality surprisingly well.

Other intermetallics are best characterized by the size ratios and packing schemes of the constituent atoms and are therefore called size-factor compounds, topologically close packed intermetallics, or *Frank – Kaspar phases*. One important group of these intermetallics are the A15 compounds. The best known size-factor compounds are the Laves phases, which form the most numerous group of intermetallics and which crystallize in the closely related hexagonal C14, cubic C15, or hexagonal C36 structures, whereby $MgZn_2$, $MgCu_2$, and $MgNi_2$, respectively, are typical examples. The valence electron concentration, however, is also an important factor here, since it decides between the three crystal structures. These crystal structures are characterized by high symmetry, high atomic coordination, and high density in close analogy to metals, and indeed the *Laves phases* show primarily metallic bonding according to the scarce information available.

Compounds which form by a phase transition with lowering of crystal symmetry from the solid solution of the constituent elements at a transition temperature below the melting temperature are known as *Kurnakov phases*. In the simplest case the phase transition results from an ordering reaction in the solid-solution lattice in which a superlattice structure is established. Examples for compound formation by atomic ordering are the compounds Fe_3Al with $D0_3$ structure, which is formed by two-step ordering from the bcc solid solution, as well as Ni_3Fe with $L1_2$ structure, CuAu with $L1_0$ structure, and Cu_3Au with $L1_2$ structure, the latter three of which form from fcc solid solutions. This atomic ordering with superlattice formation clearly results from stronger bonding between unlike atoms compared with bonding to like atoms. The difference in bonding energy between unlike and like atoms is usually known as interaction energy and corresponds to an ordering energy. Hence, higher crystal stability and higher ordering temperature are expected for a higher interaction energy. The degree of order, which depends on temperature and composition, as well as the order/disorder temperature can be modeled as a function of the interaction energy for a given compound to various degrees of approximation, for example, to a first approximation by the simple Bragg – Williams model or to a better approximation by the cluster variation or the Monte Carlo method. Apart from the degree of approximation, the predictive power of such models with respect to phase-stability and phase-diagram calculations relies on the knowledge of the interaction energy and on whether such interaction energies

are sufficient to characterize the atomic bonding state. Analyses of various transition metal systems have shown that the modeling with the cluster variation or Monte Carlo method gives good agreements with the experimental observations in most cases, whereas in some compounds with bcc structures the simple Bragg – Williams model gave better results than the more sophisticated models.

It follows that single simple atomic parameters like the interaction energy, atomic size, or valence electron concentration have only a limited validity and are generally not sufficient for predicting the stability of a compound as a function of the constituent elements. A better and more general correlation between the atomic properties and the compound crystal structure should be obtained if the particularities of the electron configurations of the constituent atoms are taken into account; these are reflected in the positions in the periodic table of elements. A better correlation has indeed been found, but the resulting structure maps still have their limitations because the changes in electron configuration due to compound formation are not considered.

It must be concluded that the bonding character and crystal structure of an intermetallic compound can be predicted in a significant way only on the basis of quantum-mechanical ab initio calculations on the respective compound. Much progress has been made in this respect, and for various important compounds with not too complicated structures the crystal energy has been calculated as a function of lattice structure in order to determine the compound stability. However, these calculations are very time-consuming even in simple cases and more progress is necessary in the future in order to give guidance to practical materials developments on the basis of multinary compounds with less simple crystal structures.

The intermetallics do not form a homogeneous group of materials. Instead the term intermetallics comprises a huge variety of compounds which differ drastically with respect to bonding, crystal structure, and properties. Therefore, properties of intermetallics cannot be discussed generally for all intermetallics, but can be discussed only by referring to specific groups of intermetallics.

It might be supposed that the particular crystal structure of an intermetallic reflects the character and strength of bonding in a systematic way and that crystal structure would be a good criterion for compound classification. However, this does not mean that intermetallics with the same crystal structure are similar with respect to bonding and properties. For example, the B2 structure is common to the intermetallic NiAl and to the purely ionic salt CsCl, and in the case of the transition-metal disilicides with hexagonal C40 structure, $NbSi_2$ is metallic but $CrSi_2$ is a semiconductor. Recent ab initio calculations showed that atomic coordination and connectivity is more relevant to crystal energy and stability than symmetry. In view of the complexity of the classification of intermetallics, intermetallics are often grouped according to more practical criteria which refer to similarities in behavior.

2.2. Basic Properties

A basic property is the melting temperature since materials parameters which characterize the deformation behavior are well correlated with the melting temperature. Examples are the elastic moduli, which not only control the elastic deformation, but are also important parameters for describing plastic deformation, and the diffusion coefficients, which determine not only the kinetics of phase reactions, but also the kinetics of high-temperature deformation, that is, creep. Furthermore, the melting temperature is intuitively regarded as a measure of compound stability, since it limits the application temperature range.

However, a compound melts when the Gibbs energy of the solid phase, which is a thermodynamic state function and which controls the phase stability, is higher than that of the liquid phase. The Gibbs energy of a phase is given by the enthalpy and the product of entropy and temperature, that is, its temperature dependence is determined primarily by the entropy. Hence, the melting temperature depends on the differences in enthalpy and entropy between the solid and liquid states and is a rather complex function of the bonding strength. Only the enthalpy is directly related to the internal crystal energy, which is determined by the bonding strength.

Nevertheless, the melting temperature correlates surprisingly well with the enthalpy of formation for sufficiently similar compounds.

It may be concluded that the enthalpy of compound formation may be a better parameter for characterizing bonding strength and compound stability and for correlating this with fundamental properties such as elastic moduli. Formation enthalpies have been determined experimentally, and they can be calculated by quantum-mechanical calculations or estimated by more or less empirical approaches.

However, the conventional formation enthalpy values refer to compound formation from the constituent elements at room temperature, that is, from the solid elemental crystals, and thus these formation enthalpies characterize only bonding strength changes during compound formation. For the complete characterization of bonding strength the total compound enthalpy must be considered, which refers to compound formation from the elements in the gaseous state. The total enthalpy of a compound may be estimated by adding the formation enthalpy and the enthalpies of fusion and vaporization of the constituent elements. As an example, data for the Ni – Al system show a good agreement of estimates with experimental data. Since the formation enthalpies are small compared with the total enthalpies, the enthalpies of the constituent elements are the major contributions to the total enthalpies.

The correlation between the total enthalpy of a compound and Young's modulus, which is one of the three elastic moduli, has been checked for various cubic compounds: for the fcc elements Al and Ni (A1), the fcc-ordered Ni_3Al ($L1_2$), the bcc-ordered FeAl, NiAl, and CoAl (B2), and the cubic Laves phases $CaAl_2$, YAl_2, $LaAl_2$, $NbCr_2$, $ZrCo_2$ and $HfCo_2$ (C15). The correlation is quite good for the Laves phases, in that there seems to be a common scatter band, near which the data of some other compounds lie. However, the data points may be subject to appreciable experimental uncertainties, as indicated by data for Ni_3Al. Such uncertainties for Young's modulus may be due to differences in microstructure, that is, texture and artefacts. Apart from this, the data for the B2 compounds show that Young's modulus is not a simple function of the enthalpy of the compound. This must be expected because Young's modulus is a complex function of the potential wells of the atoms, which cannot be characterized by a single parameter. A similar correlation has been found for the activation energy of diffusion.

It must be concluded that there are physically justified correlations between parameters which characterize bonding strength and compound stability and the macroscopic compound behavior. However, such correlations represent complex functional relationships, and hence they are useful only for order-of-magnitude predictions. More quantitative predictions have to consider the character and strength of bonding in a more detailed way, that is, they have to rely on quantum mechanical calculations which are cumbersome and time-consuming.

Recently, fundamental properties, especially elastic moduli, of various simple compounds have been studied by ab initio calculations, and much progress has been made in this field. Thus, a basic understanding of the bonding character of, for example, transition metal aluminides was reached, and it was shown that the degree of directional *d*-electron bonding determines the ideal cleavage strength. However, it has also been shown for B2 transition-metal aluminides that the ductility or brittleness is too complex a function of strength and character of bonding for establishing simple relations between electron distribution parameters and mechanical properties.

2.3. Criteria for Compound Selection

Candidate compounds for materials developments are selected in view of specific applications, that is, they must show certain properties which make them promising for a particular application. For permanent magnets the "energy product" $(BH)_{\max}$ (B = magnetic induction, H = magnetic field strength) is a figure of merit and should reach high values whereas for other functional materials other physical parameters are decisive.

Intermetallic compounds for structural applications must show a sufficient strength at service temperature which also means a sufficient creep resistance. The creep resistance is correlated with the diffusion coefficient and with the shear modulus, and both parameters in turn with the melting temperature. Hence, the candidate com-

pound should have a sufficiently high melting temperature. The limiting temperature for structural applications of conventional metallic alloys is of the order of 75 % of the melting temperature in many cases. The most advanced high-temperature alloys are the Ni-based superalloys, which are used in gas turbines with service temperatures of up to about 1100 °C. Hence compounds with melting temperatures above 1600 °C must be considered if application temperatures above those of superalloys are aimed at. High-melting compounds may form low-melting eutectics that can affect the stability of the compound during processing or service, and therefore such compounds with low-melting eutectics should be avoided.

For many functional and structural applications density is a very important and sometimes decisive parameter. Structural intermetallics for moving components must show a sufficiently high specific strength, which is the ratio of strength to density and has the dimension of length. The specific fracture strength, that is, the rupture length, of advanced superalloys such as the mechanically alloyed oxide dispersion strengthened (ODS) superalloy MA 6000 is of the order of 15 km, which would have to be surpassed by new structural materials. Compounds which contain light elements — e.g. Ti, Al, Si, Mg — may have such a low density that they compare favorably with conventional alloys in spite of lower strength or restricted temperature range.

The main problem of strong intermetallics is their brittleness, which makes processing and application difficult or impossible. However, the brittleness of intermetallics should be less severe than that of ceramics because the atomic bonding of intermetallics is at least partially metallic, whereas it is primarily covalent or ionic in ceramics. This is illustrated by the temperature dependence of yield stress and deformability of the intermetallic NiAl in comparison with that of nickel on the one hand and of silicon and alumina on the other hand. NiAl which is a candidate compound for high-temperature applications softens with rising temperature at about half the melting temperature T_m, which is the range of Si with covalent bonding and which is higher than that of the ceramic Al_2O_3. However, the brittle-to-ductile transition temperature is about 0.4 T_m for NiAl whereas it is above 0.8 T_m for Si and Al_2O_3, that is, the deformation behavior of such an intermetallic may be regarded as intermediate between those of metals and ceramics.

Plastic deformation is more difficult in intermetallics than in metals and conventional metal alloys because of the stronger atomic bonding and the resulting ordered atom distribution, which gives rise to more complex crystal structures. The brittleness of intermetallics increases with decreasing lattice symmetry and increasing unit cell size. Therefore intermetallics with high crystal symmetry — possibly cubic compounds — and small unit cells are preferred for developing new structural materials. Indeed the candidate compounds FeAl, NiAl, Fe_3Al, Ni_3Al, TiAl for development of structural materials have crystal structures which are cubic (B2, $D0_3$ or $L2_1$, $L1_2$, $L'1_2$) or nearly cubic, that is, tetragonally distorted ($L1_0$, $D0_{22}$).

However, even for such selected compounds, brittleness remains a problem, and the causes for this are manifold. A material fractures in a brittle manner if there is no plastic deformation and stress relaxation at the crack tip, that is, the yield stress is higher than the stress for cleavage or fracture. The reason for this may be an insufficient number and/or mobility of dislocations and/or an insufficient number of slip systems. Since these parameters depend not only on crystal symmetry but also on the specific characteristics of the particular compounds, the aim of compound selection and composition variation by alloying must be dislocations with low energy and high mobility and at least five independent deformation modes (i.e. dislocation slip systems and twinning systems), which are necessary for general homogeneous plastic deformation according to the Von Mises criterion. Crystal anisotropy is an important factor in brittleness, and criteria are used which rely on elastic moduli relations. Brittle fracture may be a result of weak grain boundaries and other microstructure heterogeneities leading to localized deformation and stress concentrations. The disproportion of yield stress and fracture stress may also be due to a very low surface energy, which makes cleavage and cracking easy. This may be aggravated by the segregation of impurities, which usually lower surface energies. Impurities, in particular oxygen and hydrogen, may enter the material from the environment, so en-

vironmental embrittlement is an important issue for many intermetallics. A detailed knowledge of the thermodynamics and kinetics of the particular alloy system is necessary for a reduction of the various embrittling effects.

Intermetallics for any application must be corrosion resistant in the operating environment. For high-temperature applications this means oxidation resistance in many cases. Oxidation resistance is provided by the presence of elements, in particular Cr, Al, Si, which can form protective oxide layers. However, chromium oxide is volatile above 1000 °C and silicon oxide may form low-melting silicates. Therefore, aluminides are strongly favored for high-temperature applications. To act as protective layers, the scales must show a sufficient density and adherence, which may be improved by alloying with further elements (macroalloying) and in particular by adding minor amounts of "active" elements such as Ti, Zr, Hf (microalloying). Furthermore, scales must show sufficient long-term stability, which also means mechanical stability, that is, they must tolerate strains, for example, during creep, without being damaged. In the case of insufficient oxidation resistance protective coatings may be applied. However, the thermal stability of such coatings decreases with increasing temperature because of increasing reaction and diffusion rates and therefore intermetallics for applications above 1100 °C should be inherently oxidation-resistant.

Finally, it must already be possible to prepare an intermetallic with sufficient quality in the laboratory, and from a practical point of view this is the basic requirement for any materials development. The processing of high-strength intermetallics is difficult because of their brittleness, and the development of the necessary processing techniques is a very demanding task. It is, however, also a very important task, because a poor quality increases the apparent brittleness and reduces the strength, and this may then preclude any applications of the tested material.

3. Magnetic Materials

3.1. AlNiCo Alloys

The advantageous magnetic properties of Fe – Ni – Al alloys with suitable composition were first discovered by Mishima in 1931, and this initiated the development of the AlNiCo alloys for applications as permanent magnets (→ Magnetic Materials, → Cobalt and Cobalt Compounds, Chap. 6.3). The basic alloy contains about 50 atom % Fe, 25 atom % Ni, and 25 atom % Al, to which various other elements (Co, Cu as macroalloying elements and Nb, Ti as microalloying elements) are added for property optimization. The alloys are single-phase at high temperatures and decompose spinodally on cooling at a controlled rate to form a two-phase microstructure with interlocking phase distribution. The additional alloying elements Co, Mn, Ti, and Cu, which dissolve preferentially in the B2 compound, and Cr, Mo, V, Nb, and Si, which dissolve preferentially in the disordered Fe-rich compound, control the decomposition process of the AlNiCo alloys. The constituent phases of these alloys are the weakly ferromagnetic NiAl base compound with B2 structure and the strongly ferromagnetic, disordered bcc Fe-rich compound. The interlocking phase distribution and the strong shape anisotropy of the Fe-rich compound result in high coercivity. The magnetic behavior is a sensitive function of pretreatment.

AlNiCo alloys, which are produced by casting or sintering, are brittle and hard; they can be machined only by grinding, spark erosion, and electrochemical milling, and they resist atmospheric corrosion well up to 500 °C. The magnetic properties are summarized and compared to those of other alloys in [10 – 12]. AlNiCo alloys are superior to other permanent magnet materials in resisting the effects of temperature on magnetic properties. Presently, NiAl is also considered an attractive candidate compound for other functional applications, for example, contacts in thin-film electronic devices or high-voltage electrodes in electron-optical instruments.

3.2. FeCo Alloys

Permendur, an FeCo alloy containing 2 % V, is a soft magnetic material with high saturation induction (e.g., for electromagnet pole tips [12] (→ Magnetic Materials). These alloys also exhibit a high positive magnetostrictive coefficient, which has made them useful in sonar transducers

and in high-accuracy positioning devices. Similar Fe – Co – V alloys with more V and less Fe are known as Vicalloy alloys.

The B2 compound FeCo is stable only at temperatures below 730 °C and has a broad range of homogeneity. At 730 °C there is an order – disorder transition with 0.2 % change in volume from B2 to A2 (bcc), and a further structure change from A2 to A1 (fcc) occurs at about 985 °C. The ordering reaction proceeds heterogeneously or homogeneously, depending on temperature. The ordering kinetics are affected by alloying additions, and in particular alloying with 2 atom % V reduces the ordering rate significantly and allows the freezing of the high-temperature disordered structure by quenching to low temperatures. The addition of more than 2 % V leads to alloy decomposition, as is indicated by the Fe – Co – V phase diagram. A still larger effect on the ordering kinetics is produced by alloying with Cr. Below the critical temperature of ordering the degree of long-range order at equilibrium increases continuously from 0 at 730 °C to 0.9 at 500 °C and approaches 1 (perfect order) asymptotically at low temperatures.

The mechanical behavior of FeCo has been studied intensively including creep, fatigue, and fracture. At room temperature FeCo is ductile, with 15 % uniform elongation and subsequent necking, in the disordered state, that is, after quenching from above the ordering temperature, whereas in the ordered state, that is, after annealing below the ordering temperature, it shows only little ductility with 5 % uniform elongation and no necking. Hence cold rolling is difficult in the ordered state. Furthermore, FeCo is subject to hydrogen embrittlement at room temperature.

The flow stress increases with decreasing degree of order, that is, with rising temperature, to reach a maximum at about 700 °C just below the ordering temperature when FeCo is only partially ordered. Above the flow stress peak temperature, normal softening is observed due to thermal activation. In other words, FeCo, like other intermetallics, exhibits an anomalous positive temperature dependence of flow stress.

Ordered FeCo – 2V exhibits more homogeneous deformation and a higher strain-hardening rate than disordered FeCo – 2V at all temperatures. The yield stress and fracture stress increase with decreasing grain size according to the usual Hall – Petch relationship. The fatigue resistance is improved by ordering with only a small effect of the environment. The low ductility can be increased by adding Ni as fourth element, which changes the microstructure, and still more by thermomechanical treatment, which results in a Hall – Petch-type dependence of ductility on grain size or subgrain size. Even cold rolling can reduce the brittleness. The brittle-to-ductile transition temperature in the ordered state can be reduced significantly by deviations from stoichiometry, that is, by decreasing the Co content, which decreases the critical temperature of ordering. Positive effects on cold workability have been produced — apart from alloying with V or Cr which both slow down the ordering kinetics — by alloying with V, Nb, Ta, Cr, Mo, W, and C, whereas Be, Ti, Zr, Mn, Cu, Ag, Au, B, Al, and Si are ineffective.

Alloying of Fe and Co with precious metals leads to the compounds FePt, CoPt, FePd with $L1_0$ structure, which is an ordered fcc structure with tetragonal distortion. These compounds have been of importance for applications as permanent-magnetic materials, and in particular CoPt, which is used in the partially ordered state, excels because of isotropy, ductility, easy machinability, and resistance to corrosion and high temperatures (see also [12]). However, CoPt alloy magnets are seldom used now since these alloys have been replaced by rare earth magnets with superior magnetic properties.

3.3. Sendust Alloy

The iron aluminide Fe_3Al with DO_3 structure exhibits an outstanding high magnetic permeability which makes it useful as a magnetic material. The magnetic Fe_3Al-based alloys are known as Alfenol alloys [12]. Fe_3Al is formed on cooling by ordering reactions in the solid state that transform the bcc disordered solid solution, which is stable above about 800 °C, first into the FeAl compound with B2 structure, which is stable between about 800 °C and 550 °C, and then into Fe_3Al with the $D0_3$ structure. The magnetic properties can be improved by partial substitution of Al by Si, which does not change the crystal structure. This gave rise to the development of the Sendust alloy which is based on $Fe_3(Al,Si)$

and which has found widespread application as magnetic head material in recorders.

3.4. Laves Phases

The Laves phases, sometimes designated as Friauf – Laves phases, with AB_2 composition in the binary case form a very large group of intermetallics which crystallize with the hexagonal C14 structure, the cubic C15 structure, or the dihexagonal C36 structure. These structures are topologically close packed (tcp) structures, that is, the Laves phases belong to the family of the Frank – Kaspar phases. The stability of the three crystal structures C14, C15, and C36 is controlled by the atomic-size ratio of the atoms A and B and by the valence electron concentration of the Laves phase.

Various Laves phases have been regarded as promising for both functional and structural applications. Some transition-metal Laves phases, such as TFe_2 (T = Ti, Zr, Hf, Nb, Mo) and $NbCo_2$, as well as the closely related rare-earth Laves phases, show interesting magnetic properties as a result of the particular electronic structures. The rare-earth compounds $TbFe_2$ and $SmFe_2$, both with C15 structure, exhibit huge magnetostrictions at room temperature. In addition there is a magnetoelastic interaction, that is, unusual changes in elastic moduli are observed in a magnetic field. The ternary C15 compound $(Tb_{1-x}Dy_x)Fe_2$, which is known as Terfenol-D, has much potential for applications as a high-power transducer, since it combines a large magnetostriction with a vanishing magnetic anisotropy (for $x \approx \pm\, 0.7$). Like other Laves phases, this material is brittle, with an apparent brittle-to-ductile transition temperature of about 875 °C.

Various rare earth (R) Laves phases, especially RFe_2, can absorb large amounts of hydrogen (see Section 10.2) which may affect their structures, that is, they can undergo structure transformations on hydrogenation, including amorphization, which may be accompanied by decomposition reactions. Such hydrogenation and dehydrogenation reactions have been used for producing fine-grained powders for the powder metallurgical production of so-called giant-magnetostrictive RFe_2 alloys.

3.5. Rare-Earth Compounds

There is a multitude of intermetallic rare earth compounds. The complex crystal structures of these compounds are derived from few basic structures, such as the cubic $D2_1$ structure or the hexagonal $D2_d$ structure, by stacking the structural units in different ways from which the various stoichiometries result. The crystallographic data of most binary, ternary, and quaternary rare earth compounds have been compiled. The rare earth intermetallics are mostly line compounds and have only very narrow composition ranges. The preparation of the compounds is difficult because of the high affinity of the rare earths for oxygen, which leads to reactions with common crucible materials. Various processes have been developed for the preparation of intermetallic rare earth compounds.

The rare earth intermetallics have won a great practical importance because of their outstanding magnetic properties, which depend on composition and crystal structure. $SmCo_5$ and Sm_2Co_{17} led to the development of the rare earth permanent magnets (REPM) which excel by their high energy product $(BH)_{\max}$ and their high coercivity (→ Magnetic Materials). Optimized property spectra have been achieved by substituting other rare earth metals for Sm and Fe and other transition metals and Cu for Co and by appropriate processing. The resulting multinary materials have complex multiphase structures, and the effects of the various structural features on the magnetic properties have not yet been understood completely.

Alloying with the interstitials B, C, and N led to ternary rare earth compounds with very attractive magnetic properties, and outstanding examples are $Sm_2Fe_{17}C_x$, $Sm_2Fe_{17}N_x$, $Nd_2Fe_{14}B$, and $Nd_2Fe_{14}C$. $Nd_2Fe_{14}B$ has become the basis for the development of the Nd – Fe – B permanent magnets, which have an even higher energy product $(BH)_{\max}$ at room temperature than the $SmCo_5$-type and Sm_2Co_{17}-type materials at lower cost; however their behavior at elevated temperatures is less satisfactory. The various REPM materials — $SmCo_5$ type, Sm_2Co_{17} type, $Nd_2Fe_{14}B$ type — are produced primarily by powder metallurgy, though ingot metallurgy and rapid solidification have also been used. The materials are brittle, which makes machining

difficult, and their corrosion resistance is low, which necessitates protective coatings in corrosive environments. $SmCo_5$ suffers an environmental degradation of coercivity due to hydrogen absorption. The hydrogenation of the Nd – Fe – B alloys leads to structure transformation and decomposition reactions and is used for producing fine-grained Nd – Fe – B powders. Because of their most advantageous combination of properties, the rare earth magnets have found a huge market with a broad field of applications. Research and development is rapidly progressing [10, 13].

4. Superconducting Materials

4.1. Laves Phases

A transition to superconductivity at low temperatures has been observed for a large number of Laves phases with C14 or C15 structure. $(Hf,Zr)V_2$ with C15 structure is of particular interest because of its advantageous superconducting properties, since it combines a fairly high critical temperature with a high critical current density and critical magnetic field strength. Processing is difficult because of its poor deformability. Further alloying, in particular with Nb, improves the mechanical behavior to such an extent that multifilament superconductors can be produced which are considered for application in fusion reactor magnets since the superconducting properties are comparatively insensitive to neutron irradiation and mechanical strain. Room-temperature deformation of HfV_2-base alloys occurs primarily by twinning. The Hf – V – Nb phase diagram is available.

4.2. A15 Compounds

The A15 crystal structure is a complex cubic structure derived from the bcc lattice (A2) with eight atoms per unit cell. It is a typical example of the topologically close packed (tcp) structures which result from the stacking of polyhedra of various shapes to accommodate atoms of different sizes. These tcp structures allow a closer packing of atoms of different sizes than the geometrically close packed fcc (A1) and hcp (A3) structures. The A15 structure may be regarded as the basis of the family of compounds with tcp structures which are known as Frank – Kaspar phases.

The compounds with A15 structure form a large and comparatively homogeneous group of intermetallic compounds and are of enormous practical importance since many of them are superconductors (→ Superconductors, Chap. 3.1). Some of them, namely, V_3Ga, V_3Si, Nb_3Al, Nb_3Ga, Nb_3Ge, and Nb_3Sn, exhibit critical temperatures between 15 and 23 K which are only surpassed by those of the ceramic superconductors on the basis of perovskite-type oxides. However, the latter are inferior with respect to critical current density, and the best combination of critical temperature, critical current density, and critical magnetic field strength is found in the A15 superconductors, which have found wide application [12, 14].

The processing of the A15 compounds is difficult because of their brittleness. In the following, various A15 compounds, which have already been applied or have been considered for application, are briefly overviewed.

4.2.1. V_3Si

V_3Si was the first A15 compound discovered to be superconducting, with a critical temperature of 17 K. Stoichiometric V_3Si melts congruently at 1925 °C and is stable at high and low temperatures. A deviation from stoichiometry is possible on the Si-poor side, but reduces the critical temperature due to the resulting constitutional disorder. The critical temperature is also lowered by dissolved hydrogen. Likewise the critical current density and the critical field strength are reduced by elastic tensile or compressive strain. Slightly above the critical temperature, V_3Si transforms martensitically into a weakly tetragonal, still superconducting compound with twin-related thin lamellae. Prior plastic deformation with large strains at high temperatures stabilizes the tetragonal martensitic phase even at temperatures above the martensite formation temperature. The martensitic transformation gives rise to superelasticity and a shape-memory effect.

V_3Si has a high Young's modulus of 213 GPa and an apparent brittle-to-ductile transition temperature (BDTT) of the order of 1200 °C. The

plastic deformation behavior above the BDTT has been studied in detail. The creep behavior is characterized by a comparatively high activation energy in the range of 2 – 11 eV per atom that depends on stress and composition. Creep can be enhanced by superimposed electric currents.

The transition from superconduction to normal conduction in A15 superconductors occurs by the penetration of small fluxoids, that is, quantized magnetic flux vortices, which is characteristic for the type II high-field superconductors. These fluxoids can be pinned by microstructural inhomogeneities, in particular grain boundaries and precipitated particles, and this is beneficial with respect to critical current density and field strength. Consequently, microstructural changes by prior plastic straining with or without recrystallization affect the superconducting properties. The thin lamellae, which are produced by the above-mentioned martensitic transformation, are less effective with respect to flux pinning than grain boundaries, so that their effect on the superconducting properties becomes relevant only in single crystals.

V_3Si is of interest for applications because of its favorable superconducting properties and its high stability. Apart from hot extrusion, V_3Si can be deformed plastically at room temperature in spite of its brittleness by superimposing a high hydrostatic pressure, which makes the production of multifilament superconducting wires feasible for applications in solenoid magnets. Laminar V_3Si can be prepared by solid-state thin-film reactions between V and SiO_2 on Si substrates. However, Nb_3Sn has been found more favorable with respect to superconducting properties, mechanical behavior and processing, and this has precluded the application of V_3Si.

4.2.2. V_3Ga

V_3Ga with A15 structure is stable only up to 1300 °C where it transforms congruently into a V – Ga disordered bcc solid solution. There are indications for a martensitic transformation at very low temperatures, in close analogy to V_3Si, although the conditions for martensite formation are not yet clear for V_3Ga. It has a broad range of homogeneity centered around the stoichiometric composition, that is, it is very stable with respect to deviations from stoichiometry. Because of this stability, which is advantageous for fabrication, and the high critical temperature of about 16 K, V_3Ga is of interest for applications.

The superconducting properties and the deformation behavior of V_3Ga are similar to those of V_3Si. The superconduction transition can be affected by prior plastic deformation. V_3Ga is ductile in compression above 1000 °C and the creep behavior has been studied in detail. As in the case of V_3Si, V_3Ga can be deformed plastically by hot extrusion and at room temperature by superimposing a high hydrostatic pressure which makes the production of multifilament superconducting wires feasible for applications in solenoid magnets. Hybrid high-field magnets with V_3Ga tape coils have been produced successfully. However, Nb_3Sn has been found more favorable with respect to superconducting properties, mechanical behavior, and processing, and this has precluded the commercialization of V_3Ga up to now.

4.2.3. Nb_3Sn

Nb_3Sn with A15 structure forms peritectically at 2130 °C from the liquid solution and solid Nb and is stable only above 775 °C where it decomposes eutectically. The decomposition reaction can be suppressed by not too slow cooling, so that Nb_3Sn with A15 structure is maintained at lower temperatures in a metastable condition. Nb_3Sn transforms into a twinned tetragonal martensite at 43 K, and the transition to superconductivity occurs at about 18 K. This critical temperature is lowered by deviations from stoichiometry, which affect the atomic order, and by elastic strain. Small increases in the critical temperature are possible by addition of ternary alloying components. The transition temperature does not depend sensitively on prior plastic deformation.

Like the other A15 compounds, Nb_3Sn can be deformed readily at high temperatures, e.g., by hot extrusion, whereas deformation at low temperatures is possible only by superimposing a high hydrostatic pressure. The high temperature deformation and creep behavior has been studied in detail, and a beneficial effect of grain size reduction on the brittle-to-ductile transition temperature (BDTT) has been found.

Nb_3Sn superconductors with multifilament geometry, which are needed for electromagnet applications, are easily fabricated by the so-called bronze process which has lead to the widespread commercial application of Nb_3Sn. In the bronze process Nb rods are inserted in a bronze rod or tube which is then processed to obtain a multifilament wire. After wire processing, Nb_3Sn shells are formed around the Nb cores by reaction heat treatments. The final multifilament composite superconductor consists of Nb_3Sn fibers with Nb cores which are embedded in a bronze matrix; the latter is surrounded by a coating of Nb, which serves as a diffusion barrier, and an outer Cu tube, which serves as a stabilizer and carries the current in the case of transition to normal conduction. Various specific processing routes, including powder metallurgy, have been developed for optimized superconductor production, and hybrid superconductor coils are commercially available.

The superconducting properties of the composite superconductor as well as the mechanical properties depend on the particular microstructure which is a function of the various prior processing steps. Much work has been directed at the details of the various processes, e.g. the effects of alloying additions, the diffusion of Sn during Nb_3Sn formation, the grain size dependence of the flux pinning force and the tensile strength and fracture at room temperature, or the effects of the hardnesses of the constituent phases on the composite workability. Recent new developments rely on the beneficial effects of additions of Ti, Hf, Ta, and/or Ge on the superconducting properties.

4.2.4. Nb_3Al

Nb_3Al with A15 structure forms peritectically at 2060 °C and is stable below this temperature in the whole temperature range only with Al-deficient off-stoichiometric compositions. The stoichiometric composition corresponds to the maximum solubility of Al in Nb_3Al and is reached only at 1940 °C in eutectic equilibrium with the liquid and the σ-phase Nb_2Al. The transition to superconduction occurs at 19 K and there is no martensitic transformation. The transition temperature of Nb_3Al is affected by deviations from stoichiometry and perfect order like the other A15 compounds, but in a less sensitive way. The A15 compound with the highest transition temperature is Nb_3Ge, which can be alloyed with Nb_3Al to form the ternary A15 compound $Nb_3(Al_{0.7}Ge_{0.3})$ with the highest critical field strength.

Nb_3Al has long been considered for electromagnet applications because of its advantageous superconducting properties. However, the processing of Nb_3Al is very difficult because of its brittleness of Nb_3Al. Powder metallurgy has been used successfully for preparing Nb_3Al by reaction synthesis and producing, e.g., a Nb_3Al – Ag composite superconductor. Nb_3Al tapes have been prepared by rapid solidification. A novel process with thin Nb – Al sandwiches as starting material has allowed the fabrication of Nb_3Al superconducting wires with good workability. Furthermore various other processes have been used successfully for producing Nb_3Al wires.

4.2.5. Nb_3Si

Nb_3Si is a high-temperature line compound which forms with a tetragonal crystal structure by a peritectic reaction at 1980 °C and is stable only above 1770 °C. Rapid solidification of the liquid produces amorphous Nb_3Si. The A15 structure is unstable and is obtained only by special rapid solidification techniques and by crystallization of amorphous Nb_3Si. Nb_3Si with A15 structure is of interest because a high transition temperature for superconduction is expected, and indeed a transition temperature of 19 K was reported for near-stoichiometric Nb_3Si with A15 structure, which was prepared by crystallization of amorphous Nb_3Si under high pressure.

5. Electronic Materials

5.1. Silicides

Metal(M)-like M_2Si silicides, as well as other transition metal silicides (→ Silicon, Chap. 5), are of major importance for applications as thin-film materials in electronic devices, for example, as low-resistivity interconnects and gates, Ohmic contacts, and Schottky barriers in very large scale integrated (VLSI) circuits [16]. The

most eminent example is Pd_2Si which is used for shallow contacts with very small controlled thickness and extension. The kinetics of thin-film formation and growth are controlled by diffusion and can be optimized by alloying with further elements. The film-formation process affects the distribution of dopants in the Si substrate. Other M_2Si compounds have also been studied with respect to thin-film formation, e.g., Ni_2Si, Co_2Si,and Mg_2Si. Thin oxide layers may form on the silicide films by air exposure at room temperature, which can be a problem for Ohmic contacts or a necessity for a tunneling device.

The transition metal silicides CrSi, MnSi, FeSi, and CoSi crystallize with the cubic B20 structure, whereas NiSi and the noble metal silicides PtSi, IrSi, and PdSi crystallize with the orthorhombic B31 structure. Such MSi compounds, in particular PtSi and also NiSi, are also important thin-film materials for applications in electronic devices.

The disilicides $CrSi_2$, VSi_2, $NbSi_2$, and $TaSi_2$ crystallize with the hexagonal C40 structure. VSi_2 is of interest for applications in electronic devices. $TaSi_2$ has been successfully used in producing microprocessors and other electronic devices. $CrSi_2$ is of interest for applications as thin-film interconnectors. $CoSi_2$ with the comparatively simple cubic C1 structure is applied in large-scale integrated electronic devices. $NiSi_2$ is another compound of primary interest for applications in electronic thin-film devices. $MoSi_2$ is advantageous for applications in electronic devices either as substrate for Si films or as thin-film interconnectors in VLSI circuits. In view of these applications, the conditions for thin-film formation as well as for the formation of thin oxide layers have been studied in detail.

5.2. Other Compounds

Various aluminides, such as Al_3Ti, Al_3Hf, Al_3Ta, and Al_7Cr, are used as shunting layers in integrated circuits to improve the resistance to failure of Al-based interconnects by electromigration stressing [17].

GaAs, InP, InSb, and InAs are compounds with high electron mobilities and high saturation velocities relative to Si and hence are very attractive materials for application in high-speed devices [18]. Such devices are the GaAs metal Schottky field effect transistors (MESFETs), the high electron mobility transistors (HEMTs), the heterojunction bipolar transistors (HBTs), the permeable-base transistors (PBTs), the static inductance transistors (SITs), and the metal insulator semiconductor field effect transistors (MISFETs).

6. Electric Materials

The transition metal disilicides MSi_2 (M = Ti, Zr, Hf, V, Nb, Ta, Cr, Mo, W (→ Silicon, Chap. 5) crystallize with the tetragonal $C11_b$ structure, the hexagonal C40 structure, or the orthorhombic C49 and C54 structures and show extended mutual solid solubilities. These crystal structures are closely related since they only differ in the stacking of the same structural elements.

$MoSi_2$ with $C11_b$ structure has found widespread application as heating elements in high-temperature furnaces at up to 1700 °C because of its advantageous electrical properties and its excellent oxidation resistance. Well-known examples are Kanthal Super and Mosilit heaters. The high oxidation resistance of these materials, which is not shown by the other Mo-rich silicides, is due to the formation of a protective vitreous highly adherent SiO_2 film with prior evaporation of the volatile Mo oxide. However, $MoSi_2$ is subject to oxidative disintegration by pest oxidation at intermediate temperatures between about 300 °C and 600 °C, which occurs at grain boundaries and microstructural defects and thus can be minimized by avoiding these or by alloying with small amounts of Fe and Re.

7. Thermoelectric and Thermomagnetic Materials

7.1. Silicides

The dimagnesium monosilicide Mg_2Si is a semiconductor with a high thermoelectric power and a low thermal conductivity which is advantageous for thermoelectric power generation. The thermal conductivity can be minimized by alloying with Ge to form the ternary $Mg_2(Si,Ge)$ compound. Doping with Ag and Sb produces *p*-

and *n*-type semiconducting $Mg_2(Si,Ge)$, respectively, and the combination of both results in a thermocouple with a high efficiency for thermoelectric energy conversion. The interactions between doping, point defects, and microstructure has been studied in detail.

$FeSi_2$ is another disilicide with a high thermoelectric power and has been proposed for application in a thermoelectric power generator. It has an orthorhombic crystal structure and is stable only at lower temperatures, whereas at higher temperatures it decomposes to form a two-phase FeSi – Fe_2Si_5 alloy. Furthermore, it is subject to pest oxidation. Doping with Al produces *p*-type conducting $FeSi_2$, doping with Co produces *n*-type $FeSi_2$, and the combination of both materials gives a thermocouple which can be used as a thermoelectric power generator. Such a power-generation system for the efficient conversion of low-grade heat into electricity has been proposed [12, 19].

The monosilicides MnSi and CoSi exhibit large thermoelectric powers and thus are promising for thermoelectric power generation. In particular, a CoSi – $CrSi_2$ thermogenerator has been proposed.

The complex manganese silicide $Mn_{11}Si_{19}$ is promising for thermoelectric applications because of its anomalously high anisotropy of the thermopower over an exceptionally wide temperature range [20].

7.2. Other Thermoelectric Compounds

Thermoelectric materials on the basis of the semiconducting compound Bi_2Te_3 are widely used as thermoelectric coolers (TECs) for operation near room temperature in small refrigerators [20] (→ Refrigeration Technology, Chap. 1.4). Such materials with the rhombohedral C33 structure are solid solutions of Bi_2Te_3 with the isomorphous compounds Sb_2Te_3 and Bi_2Se_3. They easily cleave along the basal planes and show anisotropic mechanical and transport properties.

Thermoelectric materials for application at medium temperatures are based on the compound PbTe with simple cubic B1 structure, which forms solid solutions with the isomorphous compounds PbSe, PbS, SnTe, and GeTe [20]. *n*- and *p*-type materials are prepared by deviation from stoichiometry and doping with halogens as donors and alkali metals as acceptors, respectively.

Research and development are leading to novel complex alloys with even more attractive properties [21, 22].

7.3. Thermomagnetic Compounds
[23 – 27]

Magnetization of a material by application of a strong magnetic field produces magnetic order with electron spin alignment and is accompanied by heat release. Without the magnetic field the material returns to magnetic disorder with heat consumption from the surroundings. This magnetocaloric effect is used for magnetic refrigeration, which is more efficient than conventional gas compression refrigeration. For this purpose magnetic refrigerant materials with high magnetic moments are needed, since the amount of produced or consumed heat is proportional to the magnetic moment apart from the magnetic field.

Intermetallic rare earth metal compounds with transition metals show very large magnetic moments and have successfully been used for magnetic refrigeration. Present developments concentrate on optimizing such rare earth metal phases with respect to magnetic moment and temperature of operation. An outstanding example is the phase $Gd_5Si_2Ge_2$ with a magnetocaloric effect which is twice as large as that of Gd [25]. The operating temperature of this material can be tuned from about −240 to about +20 °C by adjustment of the Si/Ge ratio.

The materials developments aim at magnetic refrigerators which can be applied, e.g., as small cryocoolers for cooling superconductive devices to near liquid helium temperatures or as large commercial liquefiers for liquefying cryofuels.

8. Optical Materials

Various intermetallics show beautiful colors which may be attractive for applications in jewelry. An early example is the Regulus of Venus of the alchemists with its bright violet color, which results from the reduction of Sb_2S_3, the

ore of antimony, through the addition of copper. A more recent example is the nickel disilicide $NiSi_2$, which can be alloyed with Ni and Al to produce compounds with distinct pale blue, yellow, and white colors and variations thereof. Au – Cu – Ag alloys on the basis of the intermetallic compounds CuAu and Cu_3Au, which have found applications in dentistry, excel by virtue of their decorative gold color. Likewise, PdIn with its gold color is promising for dental prosthetics and jewelry. A further example is the bright-purple $AuAl_2$ known as purple plague which gave rise to the Spangold alloy [28].

Apart from color, various intermetallics show optical properties such as reflectance, transmittance, absorbance and refraction, which are attractive for applications in optical devices [12]. GaAs is used for optical waveguides in integrated IR light circuits. Other applications of GaAs are optical high-power switches, high-efficiency solar cells, light-emitting diodes (LEDs), and semiconductor diode lasers. Various tellurides such as HgTe, CdTe, PbTe, SnTe, and corresponding solid solutions in which Zn and Mn beneficially substitute for Cd have been used for developing photodetectors for light from the far infrared to the visible region.

Thin films of various intermetallics such as $AuIn_2$, AuSn, InSb, BiTe, SnAs, CaSb, GeTe, and others are being developed for use as recording media in optical devices [12]. The local reflectance is changed by short laser beam pulses with subsequent slow or rapid cooling to produce a crystalline or amorphous structure, respectively. Likewise thin films of the shape-memory alloy NiTi (see Section 12.3) can be used as bistable optical memory elements.

Various ferromagnetic intermetallics are of interest in magneto-optical applications as materials for erasable optical data storage [29]. This relies on the polar Kerr effect, by which linearly polarized light experiences a rotation of the polarization plane when reflected at a magnetized material. The Kerr effect has been studied for a large number of Mn-based, Co-based, and Fe-based intermetallics. The highest potential for magneto-optical storage is attributed to MnBi and PtMnSb, besides amorphous TbFeCo-based alloys.

9. Hydrogen-Storage Materials

[30 – 35]

9.1. B2 Compounds

FeTi with B2 structure is one of the most promising intermetallic compounds for application as a hydrogen-storage material and related applications (see also → Hydrogen, Chap. 9.3.1.2). Dissolved hydrogen orders to form a substructure, whereby the B2 structure becomes rhombic, that is, a stable hydride is formed reversibly. FeTi with excess Ti is more easily hydrogenized then stoichiometric FeTi, since Ti activates the absorption and desorption of hydrogen catalytically. Second phases, including oxides, shorten the incubation time of hydrogenization, but oxygen may poison the FeTi surface at room temperature. Other B2 compounds of interest for applications as hydrogen-storage materials are CoTi and the ternary intermetallics (Fe,Co)Ti and (Fe,Ni)Ti, which show more advantageous storage properties than the binary compounds. The FeTi-base materials have good hydrogen capacities and low costs, but the problems with respect to activation, impurities, and instabilities have prevented large-scale commercial application.

9.2. Laves Phases

Various Laves phases can absorb large amounts of hydrogen and are considered for applications as hydrogen storage materials. Such AB_2 compounds contain a strong hydride former as the A element and crystallize with the C14 or C15 structure. The Laves phases with the highest sorption capacities are C15 ZrV_2 with a hydrogen-to-metal ratio H/M = 1.8, C14 or C15 $ZrCr_2$ with H/M = 1.3, C14 $ZrMn_2$ and C14 or C15 $TiCr_2$ with H/M = 1.2. $LaNi_2$, which was known as a C15 compound, with H/M = 1.5 is a tetragonal pseudo-Laves phase which is stabilized only by the presence of impurities according to recent findings.

The hydrides formed in these binary Laves phases are too stable for easy hydrogen desorption, which is a prerequisite for hydrogen storage. The hydride stability can be reduced and adjusted to practical hydrogen storage conditions by deviations from stoichiometry, substitution

of the B element, primarily by Fe, Co, Ni, Cu, Mn, Cr, substitution of the A element, primarily by Ti, or any combination of these alloying possibilities.

An example for the stoichiometry effect is given by $ZrMn_2$ which exhibits an increasing hydrogen vapor pressure with increasing Mn content and which is stable with C14 structure up to $ZrMn_{3.8}$. Another example is C14 $TiMn_2$, which reaches its maximum H solubility at the off-stoichiometric composition corresponding to $TiMn_{1.5}$, whereas it does not absorb H at the stoichiometric composition. The effects of substitution on electronic structure, alloy stability, hydride stability and H storage capacity have been studied for various systems, e.g., $(Zr_xTi_{1-x})Mn_2$, $Zr(Mn_{1-x}Fe_x)_{2+y}$, $Zr(V_{1-x}Co_x)_2$, in which both V and Co are substituted for by other transition metals, and $Zr(Cr_{1-x}V_x)_2$. $Zr(Cr_{1-x}V_x)_2$ exhibits polytypism, that is, crystal structure variants of either the hexagonal C14 structure or the cubic C15 structure are formed, which only differ in the stacking of crystal structure units. The thermodynamics of hydrogenation have been studied, and hydride formation enthalpies determined. The optimization of properties has led to multinary Laves phases such as Zr – Mn – Co – V alloys, Zr – Mn – Ni – V alloys, Zr – Mn – Ni – V – Cr alloys, or Zr – Ti – Mn – Fe and Zr – Ti – V – Fe alloys.

In summary, the Laves phase materials are advantageous because of their good hydrogen capacities in the temperature range 0 – 100 °C and low costs.

9.3. Rare Earth Metal Compounds and Other Phases

Various rare earth compounds can absorb large amounts of hydrogen and are of major interest for applications as hydrogen-storage materials, as is exemplified by RCo_3 and RFe_3. The most outstanding examples are the RNi_5 compounds, in particular $LaNi_5$, which may be regarded as a prototype hydrogen storage material (see also Chapter 10). The stability of $LaNi_5$ is affected by absorption – desorption cycling due to surface degradation processes. The property spectrum has been optimized by alloying with further elements, as is exemplified by the development of $La_{0.8}Nd_{0.2}Ni_{2.5}Co_{2.4}Si_{0.1}$ or $MmNi_{3.5}Co_{0.7}Al_{0.8}$ (Mm = mixed metal). The permanent-magnet compound $SmCo_5$ can also absorb large quantities of hydrogen which, however, reduces its coercive force. $CaNi_5$, which is isostructural with $LaNi_5$, shows an analogous behavior and is considered as a low-cost candidate for hydrogen storage.

Research and development aim at producing nanostructured materials, which can be obtained by powder-metallurgical processing through hydrogenation [32]. Such materials promise more advantageous storage properties because of their much-increased internal interface area and defect density, as demonstrated for Mg_2X phases (X = Cu, Ni, Si, Ge, Sn) [37, 38]. The prevailing problem is the hysteresis accompanying the hydriding and dehydriding processes, which reflects irreversibility and contributes to the degradation of the absorption properties during long-term service [31].

10. Electrode Materials

10.1. Mg_2Ni Alloys

Mg_2Ni-base hydrogen-storage alloys are of major interest for application as active materials of metal hydride electrodes. Such materials can be prepared by powder metallurgy, and their properties have been optimized by alloying with further elements [39]. Both partial substitutions of Ti or Ce for Mg and of Mn or Co for Ni improve discharge capacity and cycle life.

10.2. Laves Phase Alloys

Various rare earth (R) Laves phases undergo amorphization on hydrogenation. RNi_2 with C15 structure is easily transformed into amorphous RNi_2 which is very stable and is being considered for applications as long-life electrodes in electrochemical nickel – hydrogen batteries.

There are many other binary and ternary Laves phases which can absorb large amounts of hydrogen (see Section 9.2). The optimization of properties has led to multinary Laves phases such as Zr – Mn – Co – V alloys, Zr –

Mn – Ni – V alloys, Zr – Mn – Ni – V – Cr alloys, or Zr – Ti – Mn – Fe and Zr – Ti – V – Fe alloys, which have been studied in detail in view of applications as electrodes in electrochemical nickel – hydrogen batteries.

These developments have led to $Zr(Ni,Mn)_2$-base materials with high rate capability and high hydrogen capacity which are regarded as highly promising for application as negative electrode in nickel – metal hydride (NiMH) batteries for electric vehicles [36, 40].

10.3. RNi_5 Alloys

The rare earth (R) compounds RNi_5, in particular $LaNi_5$, of Section 9.3 are highly promising for applications as rechargeable electrodes in nickel – metal hydride (NiMH) batteries. The rare earths can be substituted by the cheaper Mm, and further alloying for optimiztion has led, for example, to $Mm(Ni,Co,Mn,Al)_5$, which is intended for application in high-power batteries [41]. Such batteries are presently commercialized and are used in newly developed pure electric vehicles (PEV) [33, 42 – 44].

Electrode materials are of particular interest for fuel cells, which are the subject of intense worldwide developments [45].

11. Coating Materials

Coatings are used in many cases to protect high-temperature materials in corrosive environments. Various coating systems have been developed which differ in processing and properties, as exemplified for high-temperature coatings for gas turbines [46, 47]. Such coatings usually contain intermetallic compounds as a major constituent. Present-day research and development is directed not only to high-temperature corrosion resistance, but also to high-temperature wear resistance and applications as thermal barriers [48 – 50].

11.1. Aluminides

An exceptionally high oxidation resistance is shown by the B2 compound NiAl. Accordingly NiAl has long been used as a coating material. Indeed, one of the oldest processes for producing coatings is pack aluminizing, in which Al diffuses from the Al-rich pack into the alloy to be coated and forms an aluminide surface layer, which consists of NiAl in the case of Ni-base alloys. Such diffusion coatings are still extensively used for protecting turbine blades under various turbine conditions. The coating performance is improved by adding alloying additions of Cr, Si, Ta, rare earths, or precious metals by modifying the pack aluminizing process.

Besides such diffusion coatings, overlay coatings are used which are produced by depositing a specifically designed corrosion-resistant alloy on the component surface (→ High-Temperature Materials). These coating alloys, which are described by the general formula MCrAlY (M = Fe, Ni, and/or Co), again rely on the presence of MAl phases with B2 structure. The advantage of these coatings is the negligibly small chemical interaction between coating and substrate during deposition, choice of corrosion-resistant alloy composition, and the ability to deposit thicker coatings for extended service lives. During service interdiffusion occurs between coating and substrate and may result in Al depletion of the coating. Al-deficient NiAl may transform martensitically because of cooling cycles, and this promotes spalling, that is, it contributes to the degradation of the coating.

Newly developed structural high-temperature materials may lack sufficient oxidation resistance, which initiates the development of protective coating systems. For example, the titanium aluminide alloys based on TiAl have insufficient oxidation resistance (see Section 16.1). Such alloys were coated successfully through application of a protective layer of the ternary intermetallic compound $Al_{22}Ti_8Cr_3$ with $L1_2$ structure by using the pack cementation technique [51]. Other successful coatings on TiAl alloys relied on applying a Ti – Al – Cr alloy for formation of the t phase together with the Laves phase [52] or an Ni – Al alloy with NiAl formation [53] as well as aluminizing with formation of the Al-rich titanium aluminide $TiAl_2$ [54].

11.2. Silicides

The alloys of the refractory metals molybdenum, niobium, and tantalum, which have major potential for structural applications at very high temperatures, must be protected from oxidation in oxidizing environments, and this is best achieved by applying silicide coatings [55]. Niobium alloys have successfully been coated by using a newly developed pack cementation process with codeposition of Si, Ti, Cr, and Fe, which relies on the formation of the quaternary silicide $Nb_3Fe_3CrSi_6$ with partial substitution of Nb by Ti and of Fe by Co or Ni [56].

Similar silicide diffusion coatings were developed for Cr – Nb alloys, which rely on the formation of $NbSi_2$ or $CrSi_2$, depending on doping with Ge, which suppresses formation of chromium disilicide [57]. Likewise a boron-modified titanium disilicide diffusion coating process with Ge doping by pack cementation was developed for protecting Ti alloys and Ti_3Al-based alloys (see Section 16.1) from oxidation [58]. TiAl-based alloys were successfully coated by codeposition of Al and Si by pack cementation [59] or simple liquid-phase siliconizing [60].

12. Shape-Memory Materials

[61 – 65]

12.1. Cu-Base Alloys

12.1.1. Cu – Zn – Al Shape Memory Alloys

The Cu – Zn – Al shape memory alloys are derived from the intermetallic compound CuZn with B2 structure by alloying with Al, and the composition of the resulting ternary compounds is approximately described by $Cu_{1+1.3x}Zn_{1-2.3x}Al_x$. The complete ternary Cu – Zn – Al phase diagram is available. The crystal structure of the Cu – Zn – Al alloy is the disordered A2 structure at high temperatures, which transforms into the B2 structure on cooling and into the $L2_1$ structure on further cooling. These structures are stable only at elevated temperatures and are only metastable at room temperature, that is, these alloys decompose if annealed at too low temperatures.

The $L2_1$ structure can be transformed martensitically to form various types of martensite. The crystallography and thermodynamic stability of the martensite variants have been analyzed in detail. The martensite stability is correlated with elastic anomalies, as in the case of CuZn. It was shown that different types of martensite can coexist for certain compositions. In any case, the martensite formation temperature is a very sensitive function of composition and can be varied by prior thermal cycling. In particular, alloying with Mn is used to depress the martensite formation temperature.

A special feature of the Cu – Zn – Al alloys is the so-called two-way memory effect which produces a reversible shape change on cooling and heating. This effect results from martensitic transformation and retransformation after specific thermomechanical treatments, which are designated as “training”.

Processing of Cu – Zn – Al alloys poses few problems. The alloys are usually produced by induction melting. Various dopants are in use for grain refinement to improve formability. Apart from this, powder metallurgy is used for obtaining fine-grained materials. The alloys are readily hot worked in air, and cold workability decreases with increasing Al content.

12.1.2. Cu – Al – Ni Shape-Memory Alloys

The Cu – Al – Ni shape memory alloys are based on the intermetallic compound Cu_3Al with disordered A2 structure, which is usually known as β-phase and which is stable only at high temperatures between 567 and 1049 °C with compositions between 71 and 82 atom % Cu. At 567 °C this phase decomposes by a eutectoid reaction at such a sluggish rate that it can be retained with the then metastable A2 structure by cooling below this temperature. At about 500 °C the β-phase undergoes an ordering reaction to form the metastable β_1-phase with $D0_3$ structure. Both phases can be transformed martensitically by quenching to form various types of martensite, depending on Al content and quench rate.

Cu_3Al can be alloyed with Ni without changing the transformation characteristics of the compound. Both the binary Cu_3Al and the ternary $(Cu,Ni)_3Al$ show the shape-memory

effect due to the formation of thermoelastic martensite. The ternary compound has given rise to the development of the Cu – Al – Ni shape memory alloys with about 11 – 15 wt % Al and 3 – 5 wt % Ni. The deformation modes of the martensites include various twinning modes and stress-induced transformations. The shape memory effect is a two-way effect, that is, it is completely reversible. The martensite-start temperature has an upper limit of about 180 °C and can be lowered to a large degree by increasing the Al content and to a smaller degree by increasing the Ni content.

The Cu – Al – Ni alloys are advantageous because of their higher stability at higher temperatures compared with the Cu – Zn – Al alloys. However, second-phase precipitation, which embrittles the Cu – Al – Ni alloys and precludes cold working, cannot be suppressed; hence, such alloys can only be hot finished. Thermomechanical treatments and microalloying additions, in particular Mn, Ti, Zr, are used for improving the mechanical behavior. An important effect is grain refinement, which increases both fracture strength and fracture strain according to a Hall – Petch relationship. Indeed precipitated particles have been found to reduce the as-cast grain size and hinder later grain growth during annealing. The alloying additions affect the transformation and decomposition behavior, and this must be taken into account in establishing the optimum conditions for the induction of the two-way effect. Recently, the ductilizing effect of small boron additions was discovered and studied in detail with respect to transformation behavior and microstructure.

Other similar Cu-base alloys also show the shape-memory effect. Well-studied examples are the Cu – Al – Mn shape memory alloys, which order by a two-step reaction on rapid cooling, that is, the initial disordered A2 structure is transformed first into the intermediate B2 structure and then into the final $L2_1$ structure.

12.2. NiAl Alloys

Al-deficient NiAl with B2 structure is transformed martensitically by rapid cooling. This transformation is thermoelastic and produces the shape-memory effect. The martensite formation temperature increases linearly with increasing Ni content from about − 240 °C for 60 atom % Ni to about 1000 °C for 70 atom % Ni. Thus, the shape-memory effect can be produced at high temperatures, and this allows the development of high-temperature shape-memory alloys. The martensitic transformation of Ni-rich NiAl can be induced by external applied stresses; it is thermoelastic, superelasticity has been observed, and the martensite deforms by twinning and detwinning. The transformation characteristics do not depend on the processing route. The problem of the low room-temperature ductility of NiAl has been overcome by alloying with third elements, in particular Fe, to produce a ductile second phase with fcc structure.

12.3. NiTi Alloys

The intermetallic compound NiTi with B2 structure has been used since about 30 years as shape-memory alloy for couplings, fasteners, connectors, and actuators in the automotive and aerospace industries, electronics, mechanical engineering, and medical applications. NiTi is known as Nitinol, which refers to Ni and Ti and the US Naval Ordnance Laboratory where this material was developed. NiTi melts congruently at 1310 °C and has an extended homogeneity range.

NiTi transforms martensitically from the parent B2 phase to a monoclinic martensite phase with an intermediate orthorhombic R phase, from which a reversible shape-memory effect with the best shape-memory behavior of all shape-memory alloys and pseudoelasticity results. The characteristics of such shape-memory alloys have been studied in detail with respect to crystallography, microstructure, thermodynamics, kinetics, and macroscopic mechanical behavior, and applications have been described.

The shape-memory behavior of NiTi is improved by prior thermomechanical treatments which produce advantageous microstructures and textures. The transformation temperature is about 110 °C for stoichiometric NiTi and is decreased by excess Ni. Likewise the transformation temperature is lowered by alloying with Fe and Cr, whereas Cu decreases the transformation temperature hysteresis. Recently a widened transformation temperature hysteresis

was found for Ni – Ti – Nb alloys which is attractive with respect to coupling and sealing applications. The transformation temperature is increased to 500 °C by the partial substitution of Ni by Pd, which, however, affects ductility.

The elastic and plastic deformation behavior, including mechanical twinning, of NiTi alloys has been studied intensively. Noteworthy is the high ductility of NiTi, which allows deformations of up to 70 %. Furthermore the yield strength of NiTi depends on temperature in an anomalous way, that is, it increases with increasing temperature to reach a maximum, and only above this peak temperature does normal softening occur.

Processing of NiTi alloys is difficult and must be done with care to obtain the advantageous properties. Melting must be carried out in vacuum or under inert atmosphere because of the reactivity of Ti, and hence vacuum-induction, plasma-arc, and electron-beam melting are all used commercially. Hot working is possible without problems. Processing at low temperatures is difficult because of extremely high work hardening, and intermediate annealing treatments are required for cold rolling, machining, etc. The ductility problem of the (Ni,Pd)Ti alloys with high transition temperature is relieved by alloying with B. Joining by welding, brazing, or soldering is generally difficult. The excellent shape-memory behavior of the NiTi alloys is accompanied by an excellent corrosion resistance, comparable to stainless steels, which makes them the only shape-memory alloys suitable for implantation in the human body. Recently NiTi has been used as strengthening phase in Al matrix composites, which experience an additional strengthening effect due to the shape-memory effect of NiTi.

13. Medical Biomaterials [66 – 69]

Classical metallic biomaterials for medical implants and other devices are stainless steels, in particular the austenitic AISI 316L steel, Co – Cr(– Mo) alloys including Vitallium, manifold Ti alloys, i.e., commercially pure (cp) Ti, Ti6Al4V and other Ti alloys with Zr and/or Nb and/or Ta, cp Nb, cp Ta [70], and there are developments for using Mg alloys [71]. Such alloys are used usually for applications such as orthopedic implants, nails, screws, plates for fixing bones, artificial hip joints, heart valve prostheses, and stents. Problems are posed by the necessary biocompatibility, which is controlled primarily by corrosion resistance and physical alloy properties. The corrosion resistance increases with the transition from steels to Co – Cr alloys and further to Ti alloys which, however, is paralleled by respective cost increases.

In view of the advantageous corrosion behavior of the Ti alloys, intermetallic Ti – Al alloys (see Section 16.1.2) have recently attracted major interest for endoprosthetic applications, such as hip and knee prostheses and dental implants [72].

Besides the presently used biomaterials, the intermetallic phase NiTi known as Nitinol is extensively used for a wide variety of applications because of its outstanding attractive properties [73 – 75]. In addition to being biocompatible, this material is superelastic and shows the shape-memory effect (see Section 12.3). The extremely good biocompatibility is due to the formation of a passive TiO2 layer. Since NiTi is not ferromagnetic, NiTi devices are compatible with magnetic resonance imaging (MRI).

Superelastic NiTi wires are used for connecting bone fragments and fixing small bone fragments. Other applications are filters for large embolized blood clots. The superelasticity gives rise to an enormous flexibility which is made use of for producing medical instruments, e.g., superelastic NiTi catheters. The most celebrated application is the self-expanding stent, which relies on knitted or welded NiTi wire. The long-term stability of such devices is still the subject of discussion, and in particular there is the question whether toxicity may arise after many years of service.

14. Dental Materials

14.1. Amalgams

Dental amalgams have been in use for more than a thousand years. Amalgams are still a most important class of material for dental restoration in spite of corrosion problems with mercury release because they offer an advantageous combination of properties with respect to processing and use.

These amalgams are formed by alloying Ag – Sn – Cu alloys on the basis of the intermetallic compounds Ag_3Sn and Cu_3Sn with mercury. The amalgamation reaction results in the formation of a complex multiphase alloy structure which contains the phases Ag_2Hg_3, Sn_8Hg, Ag_3Sn, and Cu_6Sn_5, depending on composition.

Processing involves mixing and compaction of powders and is comparatively simple and is analogous to mechanical alloying. The amalgams must show a sufficient compressive strength and creep resistance, since the oral temperature is only about 10 % below the melting temperature. The dental amalgams are very brittle which leads to failure with tensile or bending stresses in unsupported margins. The fracture processes are correlated with corrosion processes which primarily attack the phases Sn_8Hg and Cu_6Sn_5 and lead to the release of mercury and SnO, respectively. Attempts to replace mercury in these amalgams have not yet been successful.

The alloy systems of interest have been studied in detail with respect to phase reactions, microstructure evolution, mechanical behavior including creep and fatigue, corrosion resistance and clinical performance, and the processing technologies are well established [76, 77].

14.2. Cu – Au Alloys

Au – Cu – Ag alloys on the basis of the intermetallic compounds CuAu and Cu_3Au have found applications in dentistry because of their extremely high corrosion resistance, their advantageous mechanical properties such as high strength and ductility, and their decorative gold color. These alloys age-harden as a result of complex ordering and decomposition reactions by which the phases Cu_3Au I, CuAu I, CuAu II, and an Ag-rich α_2 phase are formed, depending on composition.

Cu_3Al I is the well-known Cu_3Al compound with $L1_2$ structure, which is the prototype phase for this crystal structure. Cu_3Au II forms at intermediate temperatures with off-stoichiometric compositions and is described as either tetragonal or orthorhombic. In any case, the Cu_3Au II structure results from the $L1_2$ structure by the introduction of equally spaced antiphase boundaries (APBs). Such a structure is usually known as long-period superlattice (LPS). At the equiatomic composition the tetragonal $L1_0$ phase CuAu I forms, and again an orthorhombic LPS is observed at intermediate temperatures, which is known as CuAu II. All phases are separated from each other by two-phase equilibria.

The elastic behavior is known, as is the diffusion behavior. The deformation behavior of Cu_3Au was studied in detail to clarify the effects of atomic order, and it was found in particular that order decreases the yield stress and increases the work hardening rate while still retaining high ductility. Inversely, heavy cold deformation destroys the order. The ordering reaction produces antiphase domains which give rise to an additional strengthening effect in this and similar phases; strength increases with decreasing domain size. The domain size can be varied by prior processing, and it increases during ageing in analogy to Ostwald ripening. The Portevin – Le Chatelier effect with serrated yielding was observed for both the ordered and disordered state. Recovery and recrystallization have been analyzed in detail.

15. Wear-Resistant Materials

Intermetallic compounds are attractive in tribological applications because of various advantageous properties, such as hardness, thermal stability, and oxidation resistance, and because of their compatibility with metallic matrices [78]. Some of the oldest bearing alloys contain intermetallic compounds as is exemplified by the lead-based bearing alloys (babbits) with SbSn and possibly Cu_6Sn_5 or the bronze bearing alloys with $Cu_{32}Sn_8$ or Cu_3Al.

The ternary Laves phase MoCoSi, that is, $Mo(Co,Si)_2$, with hexagonal C14 structure has given rise to the development of wear-resistant Co – Mo – Cr – Si alloys which contain large volume fractions of the Laves phase in coarse distribution together with a Co-rich phase and are known as Tribaloys. Apart from their high strength and hardness, they show a sufficient fracture toughness of the order of 20 $MN/m^{3/2}$. These advantageous mechanical properties result in an excellent wear resistance which, in combination with an excellent corrosion resistance in various environments, makes the Tribaloys very appealing for applications in a broad

range of temperatures and environments. These alloys have been studied in detail including corrosive wear testing, according to which the Tribaloys compare favorably with conventional wear-resistant materials [78]. The low ductility of Tribaloys, which is due to the large amounts of Laves phase, can be increased by proper adjustment of alloy composition and heat treatment [79, 80].

Apart from the Tribaloys, modified structural intermetallic high-temperature alloys (see Chap. 16.1) have been proposed for application as wear-resistant alloys. An example is the novel Nicralc alloys which result from alloying Ni3Al with C to increase the hardness and which are intended as substitutes for high-temperature abrasion- and erosion-resistant cobalt alloys [81]. Other examples are superelastic NiTi (see Section 12.3) with hardening TiC dispersoids [82] and MoSi2 – SiC [83] and Fe_3Al – $Fe_3AlC_{0.5}$ composites [84].

16. Structural High-Temperature Materials

The aluminides of titanium, iron, and nickel, as well as some silicides, have been selected as bases for developments of new structural high-temperature alloys because of their high strengths at low and high temperatures, high thermal stability, high oxidation resistance, and/or low density. The problem of insufficient ductility was overcome by further alloying and optimization of microstructure, which usually resulted in multiphase alloys [85]. Research and development is in progress, and some developments are on the brink of commercialization. The basic properties of the intermetallic compounds in question and the respective phase diagrams, as well as the physical, mechanical and chemical properties of the respective developed or proposed intermetallic alloys, with emphasis on powder metallurgy processing, are summarized in [4].

16.1. Titanium Aluminide Alloys

16.1.1. Ti_3Al Alloys

The titanium aluminide Ti_3Al, often designated as the α_2 phase, shows the hexagonal $D0_{19}$ structure and a density of 4.2 g/cm^3, which make it most attractive for materials developments (→ Titanium, Titanium Alloys, and Titanium Compounds, Chap. 11.2).

The aim of the various materials developments on the basis of Ti_3Al has been to improve both strength and ductility by alloying with further elements and by controlling the microstructure. The most effective element for improving ductility is Nb, and indeed Ti_3Al-base alloys with engineering significance, that is, α_2 alloys and super-α_2 alloys, contain 10 – 30 atom % Nb. Ti_3Al-base alloys readily dissolve oxygen and hydrogen, which both produce embrittlement.

The developments of the Ti_3Al-based alloys are on the brink of commercialization. They have been produced in ingots of up to 4500 kg and are available as cast shapes or wrought forms including billets, bars, plates, and sheet. Likewise the powder metallurgy methods which have been developed for conventional titanium alloys are readily adapted and in addition other powder metallurgy methods, in particular reactive processing, have been applied to Ti_3Al-base alloys. The alloys can be machined, sheet can be deformed superplastically and diffusion bonded to form complex sheet parts, and the various manufacturing processes can be accomplished on conventional equipment. The alloys can be joined successfully by both diffusion bonding and linear friction welding.

16.1.2. TiAl Alloys

The titanium aluminide TiAl, often designated the γ-phase, crystallizes with the tetragonal $L1_0$ structure. The density of 3.76 g/cm^3 is even lower than that of Ti_3Al and has made the titanium aluminides most attractive for materials developments (→ Titanium, Titanium Alloys, and Titanium Compounds, Chap. 11.2). Single-crystalline TiAl shows an anomalous positive temperature dependence of the yield stress, that is, the yield stress increases with increasing temperature until a maximum is reached at about 600 °C, and only above the peak temperature is a normal negative temperature dependence observed.

The major problem for the application of TiAl is low ductility at room temperature. If the Al content is reduced below 50 atom % to form Ti_3Al as second phase besides TiAl, the resulting intermetallic two-phase alloys show ductilities of a few percent which are acceptable for applications. 48 atom % Al is the optimum composition for maximum room-temperature ductility of TiAl alloys. The aim of the various materials developments on the basis of TiAl is to improve both strength and ductility first by controlling the microstructure and second by alloying with further elements. Oxygen embrittles TiAl alloys, as do other interstitial impurities (N, C, B). In addition, environmental embrittlement has been found for TiAl, as for other intermetallics, which is clearly caused by the presence of atmospheric moisture.

The development of TiAl alloys is less advanced than that of the Ti_3Al-based materials because of the more severe ductility problems. However, the TiAl alloys are regarded as more promising, primarily because of the lower density and the higher application temperatures, and development activities are now concentrated on TiAl in various countries. Processing is more difficult compared with Ti_3Al alloys because of the higher brittle-to-ductile transition temperature, and hot working temperatures are outside the range of conventional titanium processing equipment, which has limited the practical ingot size to about 200 kg. Besides casting and hot working, powder metallurgy has been used for component fabrication, though there are problems of quality, availability, and cost of powder.

Cast TiAl alloys can be forged isothermally, fine-grain powder metallurgy material can be formed superplastically, as well as special cast and thermomechanically treated material, sheet of 1 – 2 mm thickness can be produced by twin-roll casting, special processes have been developed for rolling, and machining is possible, as is joining by diffusion bonding and welding. With respect to turbine-engine applications, component-fabrication techniques have been demonstrated for airfoils and compressor cases. Besides aerospace applications, interest is focused on automotive engine applications such as valves [86, 87] and turbocharger rotors [88, 89], which are nearer to realization.

More recent materials developments concentrated on Ti – Al alloys with reduced Al contents and significantly increased Nb contents of about 5 – 10 atom % for relieving the ductility problems [90].

16.2. Iron Aluminide Alloys

16.2.1. Fe_3Al Alloys

Fe_3Al is formed on cooling by ordering reactions in the solid state that transform the bcc disordered solid solution, which is stable above about 800 °C, first into the FeAl phase with B2 structure, which is stable between about 800 °C and 550 °C, and only then into Fe_3Al with the $D0_3$ structure. The critical temperature of ordering is much lower than the melting temperature, and this indicates weaker bonding between unlike atoms than in, for example, the nickel aluminides. The critical temperature of $D0_3$ ordering can be shifted to higher temperatures by as much as 250 °C by alloying with third elements, in particular Cr, Mo, Mn, Ti, and Si. Alloying with Ti is of particular interest in view of the high solubility of Ti in Fe_3Al with beneficial effects on strength and ductility [91]. Thermal vacancies are formed readily because of a low formation enthalpy, which is even lower than the migration enthalpy, and consequently there is a high concentration of vacancies at thermal equilibrium. High concentrations of vacancies formed at high temperatures are trapped even by slow cooling and contribute to strengthening. Strength and creep resistance at high temperatures can be increased significantly by proper alloying with precipitation of second phases, as has been exemplified by Fe_3Al with precipitated perovskite-type carbide and/or Laves phase particles [92, 93].

Fe_3Al is considered for structural applications since it not only shows a higher strength than comparable iron alloys, but also a high corrosion resistance in oxidizing and sulfidizing environments. Problems for application are the low ductility at ambient temperatures and the strength drop above the ordering temperature. The ductility of Fe_3Al is very sensitive to the environment, and environmental embrittlement can occur in the presence of moisture in the ambient atmosphere. Alloys have been produced by both powder metallurgy and ingot metallurgy,

including arc melting, vacuum-arc remelting, induction melting in air and vacuum, and electroslag remelting. These developments, aimed at applications such as automotive exhaust systems and resistance heating elements, are close to commercialization. Other potential applications are hot-gas filters in coal gasification plants and chemical processing equipment.

16.2.2. FeAl Alloys

FeAl is closely related to NiAl (Section 16.3.2) since both phases show the B2 structure and a complete mutual miscibility. However, FeAl melts incongruently in contrast to NiAl, and its melting temperature is lower, which indicates a lower stability and atomic bonding strength. The tensile ductility at low temperatures of polycrystalline FeAl is practically zero at the stoichiometric composition and increases with decreasing Al content, that is, increasing deviation from stoichiometry. The reported ductilities of off-stoichiometric FeAl are obtained only with well-annealed specimens, that is, if the low-temperature deformation is preceded by annealing at very low cooling rates. This behavior is supposed to be due to retained excess vacancies, which increase hardness and yield strength and decrease ductility and which are not equilibrated after high-temperature annealing with normal cooling rates. Anneals of several hundred hours at about 400 °C are recommended for producing ductility in off-stoichiometric FeAl. FeAl is subject to environmental embrittlement, which is due to the dissolution of hydrogen in FeAl at the crack tip and is reduced by increasing the deformation rate sufficiently.

In view of its reported advantageous properties and comparatively low density, FeAl is regarded as a potential structural material for high-temperature applications, and processing developments make use of both ingot and powder metallurgy. FeAl alloy compositions have been identified, e.g., for good weldability and for high corrosion and wear resistance in aggressive gasification environments. As in the case of Fe_3Al, the high-temperature strength and creep resistance of FeAl can be improved significantly by proper alloying with precipitation of hardening second phases [94, 95].

16.3. Nickel Aluminide Alloys

16.3.1. Ni_3Al alloys

Ni_3Al is the most studied and best known intermetallic compound because it has long been used as strengthening phase in the superalloys and because its ductility problems were overcome by ductilization by microalloying with boron. Hence, it can be produced and tested without major experimental difficulties, and thus it was preferred in the past for studying the behavior of intermetallics. Ni_3Al, known as the γ'-phase, crystallizes with the cubic $L1_2$ structure.

The outstanding feature of the plastic flow of Ni_3Al is the anomalous temperature dependence of the flow stress, which increases between room temperature and about 700 °C with increasing temperature to reach a maximum, and only at higher temperatures does normal softening occur. Polycrystalline Ni_3Al is brittle and fails by intergranular fracture, whereas Ni_3Al single crystals are highly ductile. The polycrystal brittleness of Ni_3Al is removed by microalloying Al-deficient Ni_3Al with B.

Exposure to air or oxygen affects the mechanical behavior of Ni_3Al, and various effects of environmental embrittlement have been observed. At about 800 °C the ductility of ductilized Ni_3Al shows a minimum which is more pronounced in air than in vacuum and which is significantly alleviated by the addition of Cr. Environmental embrittlement has also been observed at room temperature, especially in moist air, depending on Ni_3Al composition and dopant content, and it was concluded that this embrittlement is caused by hydrogen formation. Accordingly, stress corrosion cracking has been observed in aqueous environments.

Successful materials developments on the basis of Ni_3Al have resulted in a series of closely related Ni_3Al alloys for high-temperature applications. These alloys, known as nickel aluminides or advanced aluminides, generally contain B at levels below 500 ppm and Al below the stoichiometric composition to give ductility at room temperature, as well as up to 5 atom % Hf, Zr, Ta, and Mo for improving strength at high temperatures and up to 10 atom % Cr for

enhancing ductility at intermediate temperatures between 400 °C and 900 °C.

The Ni_3Al alloys compare favorably with many superalloys with respect to mechanical properties. Thus, Ni_3Al alloys enlarge the superalloy spectrum. However, they cannot compete with the advanced aerospace superalloys used in aircraft engines. Nevertheless, Ni_3Al alloys are promising for less demanding applications where good combinations of strength and resistance against fatigue, wear, including erosion and cavitation, and oxidation are needed. Ni_3Al alloys can be melted by air-induction melting with acceptable quality and by vacuum-induction melting, vacuum-arc remelting, and electroslag remelting for better qualities. Ingots up to 1500 kg and components have been cast with low or no porosity, depending on boundary conditions, hot working is possible by conventional hot forging, isothermal forging, and hot extrusion, the alloys can be cold worked, and property data are available. Most of the alloys can be welded with good quality, provided welding is performed with care and cutting is accomplished by high-speed abrasive wheels. In addition, powder-metallurgy methods have been applied successfully. The transfer process from the laboratory to large-scale production is handicapped by the limited deformability at elevated temperatures, which makes hot working difficult. The feasibility of commercial large-scale manufacturing has successfully been demonstrated by producing rolls of a Ni_3Al alloy for a steel hardening furnace by conventional foundry practice and automated welding [96].

16.3.2. NiAl Alloys

NiAl is the best known example of the intermetallic compounds with the cubic B2 structure which form one of the largest group of intermetallics. NiAl has an extended range of homogeneity and melts congruently at about 1640 °C for the stoichiometric composition with 50 atom % Al. This melting point is higher than those of the constituent elements, and this indicates strong bonding between Ni and Al and correspondingly a high phase stability with a strong tendency for atomic ordering.

NiAl shows high strength at low temperatures, a comparatively steep strength decrease at intermediate temperatures around half the melting temperature of about 680 °C for NiAl, and low strength with further softening at high temperatures. The softening at high temperatures is related to thermally activated creep processes. Deviations from stoichiometry produce constitutional defects which enhance diffusion and lead to softening at high temperatures, whereas at low temperatures these defects act as strengthening deformation obstacles. Polycrystalline NiAl is usually brittle with practically no ductility.

Unlike most other aluminides, NiAl with B2 structure exhibits excellent oxidation resistance since a protective Al_2O_3 scale is readily formed during oxidation. NiAl seems to be the only truly oxidation resistant intermetallic besides some silicides. The physical reason for this high oxidation resistance is that the Al content is sufficiently high and Al diffusion is sufficiently fast in NiAl at all temperatures for stable Al_2O_3 scales to form at the surface and to avoid internal oxidation in the bulk. Environmental embrittlement, which affects the mechanical behavior of various other intermetallics (e.g., the other B2 aluminide FeAl) has not been found for NiAl.

NiAl is advantageous for high-temperature applications because of its low density, good thermal conductivity, high melting point, and excellent oxidation resistance, whereas its limited deformability at room temperature and its low strength and creep resistance at temperatures above 1000 °C are disadvantages compared to the superalloys. The low strength at high temperatures is related to the excellent oxidation resistance, since both effects result from easy high-temperature diffusion. NiAl is regarded as highly promising for developing alloys which are competitive with superalloys, because the strength deficit is compensated by advantages in density and thermal conductivity, and respective materials developments are under way.

As conventional disordered alloys, NiAl alloys can be strengthened appreciably by second phases. Apart from the effects on strength, second phases may also be beneficial for ductility and toughness. An example for the latter is the successful development of an NiAl – Fe – Cr alloy with sufficient ductility at room temperature and strength at low and high temperatures for applications in industrial furnaces, coal-

conversion systems, and petrochemical plants [97].

For the strengthening of NiAl second phases with not too low Al contents are preferred with respect to density and oxidation resistance. There are hard and brittle ternary Laves phases with Al, such as NbNiAl and TaNiAl, which may be used for strengthening NiAl. A respective development has lead to a NiAl – Ta – Cr alloy which is not deformable at room temperature but excels in high-temperature strength, oxidation resistance, and shock resistance [98]. The alloy can be produced by both ingot metallurgy and powder metallurgy, so that components can be produced by investment casting, hot extrusion, hot isostatic pressing (HIP), powder injection molding, and isothermal forging.

16.4. Silicide Alloys

Silicides (→ Silicon, Chap. 5) were considered for high-temperature applications as early as 50 years ago because of their high strength and oxidation resistance at high temperatures. Presently the need for new structural materials for the highest temperatures has revived interest in silicides for structural applications, and respective developments are under way.

Cr_3Si with the topologically close packed cubic A15 structure is a candidate phase for high-temperature applications. The brittle Cr_3Si is alloyed with Cr to produce a ductile-phase-toughened intermetallic composite [99]. Ni_3Si with the ordered fcc $L1_2$ structure has a very high potential for structural applications because of its advantageous mechanical properties and its outstanding corrosion resistance. Alloying of Ni_3Si with Nb and Ti results in multiphase Ni_3Si alloys with dispersed Ni_3Nb and Ni_3Ti precipitates which are most promising for high-temperature applications because of their favorable mechanical and chemical properties [100].

Mg_2Si crystallizes with the fcc C1 structure, and its density is only 1.88 g/cm^3. Mg_2Si has a comparatively high strength and a low thermal expansion coefficient. However, its brittleness, with a brittle-to-ductile transition temperature of 450 °C, precludes the application of single-phase Mg_2Si. Alloying with Al produces Al-Mg_2Si alloys with brittle Mg_2Si particles in a ductile Al matrix, which has given rise to a successful alloy development.

The M_5Si_3 compounds (M = transition metal), which adopt a variety of complex crystal structures, are usually very stable congruently melting line compounds with melting temperatures above 2000 °C. The most attractive M_5Si_3 compound for structural high-temperature application is Ti_5Si_3 with the hexagonal $D8_8$ structure because of its high stability with a melting temperature of 2130 °C, its high strength and hardness, and its low density. A promising materials development is based on the combination of Ti_3Al and Ti_5Si_3 which has been further alloyed with Nb. Another candidate phase for high-temperature applications is Nb_5Si_3, which is even more stable with a melting temperature of 2484 °C and which is alloyed with Nb to relieve its brittleness. Such Nb – Nb_5Si_3 composites are alloyed with further elements to achieve an excellent balance of room-temperature toughness, high-temperature creep performance, and oxidation resistance [101, 102].

Presently, $MoSi_2$ is considered for structural high-temperature applications, and various materials developments are in progress. The brittle-to-ductile transition occurs at about 1000 °C or higher temperatures depending on microstructure and impurity content. The ductility and toughness of $MoSi_2$ can be improved by special processing routes, microalloying with C for avoiding SiO_2 layers on grain boundaries or insertion of a ductile second phase, usually an Nb-rich phase. Toughness can also be increased by embedding hard second phases, in particular ceramics, in a $MoSi_2$ matrix to hinder crack growth. $MoSi_2$-based composites reinforced by TiC, TiCN, and TiB_2 indeed showed improved hardness and bending strength compared to monolithic $MoSi_2$ [103]. Most work has concentrated on the $MoSi_2$ – SiC system. Other systems of particular interest are $MoSi_2$ – TiC and $MoSi_2$ – Al_2O_3, as well as the eutectics $MoSi_2$ – Mo_5Si_3 and $MoSi_2$ – $Er_2Mo_3Si_4$ and the ductile-phase-toughened $MoSi_2$ – Nb/Ta and $MoSi_2$ – Mo systems. More recent developments concentrate on intermetallic Mo – Si – B alloys consisting primarily of the phases Mo_3Si and Mo_5SiB_2 besides ductile-phase-toughening Mo [104 – 106]. Such composites show attractive oxidation resistances, fracture toughness, and creep strength, the bal-

ance of which depends sensitively on composition adjustment and processing. Furthermore, $MoSi_2$ has been considered as reinforcing phase in other composite systems, e.g. in an SiC matrix or in a beryllide matrix. $TiSi_2$ with orthorhombic C54 structure has also been considered for structural applications at high temperatures because of its high oxidation resistance and low density.

1. Introduction

Since the discovery of the Mössbauer effect by RUDOLF MÖSSBAUER [1–3] in 1958 this nuclear spectroscopic method has found a wide variety of applications in materials science, solid state physics, chemistry, metallurgy, and earth sciences.

So far, the Mössbauer effect has been observed for almost 100 nuclear transitions in more than 40 different elements. Not all of these transitions are suitable for actual studies, but ca. 15 – 20 elements remain that are appropriate for applications, of which the best known Mössbauer nuclide is iron, because the Mössbauer experiment is easy to perform with the 14.4 keV transition of ^{57}Fe, and iron is very abundant in nature.

This article introduces the principles of Mössbauer spectroscopy and the various types of chemical information that can be extracted from the electric and magnetic hyperfine interactions reflected in the Mössbauer spectrum. The introductory part focuses on the principles of ^{57}Fe Mössbauer spectroscopy, and then examples of typical applications are presented. Further information can be found in [4–13].

2. Principle and Experimental Conditions of Recoil-free Nuclear Resonance Fluorescence

2.1. Nuclear Resonance

The resonance absorption of electromagnetic radiation is a phenomenon well known in many branches of physics. The scattering of sodium light by sodium vapor, the excitation of a tuning fork by sound, and of a dipole by radiofrequency radiation are some familiar examples. The possibility of observing the phenomenon in nuclear transitions involving γ radiation was suggested in 1929 by KUHN [14]. However, for many years attempts to detect it remained unsuccessful, until RUDOLF MÖSSBAUER established the experimental conditions as well as the theoretical description of the occurrence of nuclear resonant absorption (fluorescence) of γ-rays [1–3]. The following conditions must be fulfilled for the observation of the Mössbauer effect.

Consider a nucleus in an excited state of energy E_e with the mean lifetime τ. Transition to the ground state of energy E_g occurs by emitting a γ quantum with the energy

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.e16_e01

Figure 1. Schematic representation of nuclear resonance absorption of γ-rays (Mössbauer effect) and nuclear resonance fluorescence

$$E_0 = \hbar w = E_e - E_g \tag{1}$$

This γ quantum may be absorbed by a nucleus of the same kind in its ground state, which thereby takes up the energy difference E_0. This phenomenon is called nuclear resonant absorption of γ-rays and is schematically depicted in Figure 1.

The fact that the lifetime τ of an excited nuclear state is finite means that its energy has a certain distribution of width Γ, which, due to the Heisenberg uncertainty relationship, is connected to τ by

$$\tau\Gamma = \hbar \tag{2}$$

Consequently, the probability for the emission of a quantum is a function of the energy, or, in other words, the energy spectrum exhibits an intensity distribution $I(E)$ about a maximum at E_0 with a width at half maximum Γ which corresponds to the uncertainty in energy of the excited nuclear state. The explicit shape of this distribution is Lorentzian according to

$$I(E) \propto \frac{\Gamma/2\pi}{(E - E_0)^2 + (\Gamma/2\pi)^2} \tag{3}$$

The mean lifetime τ of the excited states of the Mössbauer isotopes are in the range of 10^{-6} to 10^{-10} s; the corresponding uncertainties of the transition energies are between 10^{-9} and 10^{-5} eV. Nuclear resonance fluorescence has a remarkably high energy resolution, given by the ratio Γ/E_0, which is on the order of 10^{-12}. As an example, the first excited state of ^{57}Fe has a mean lifetime $\tau = 141$ ns, which leads to a natural linewidth $\Gamma = \hbar/\tau = 4.7 \times 10^{-9}$ eV and hence to a relative energy resolution of $\Gamma/E_0 = 3.3 \times 10^{-13}$.

The absorption line is also described by a Lorentzian curve. Nuclear resonant absorption can only be observed when the difference of the transition energies for emission and absorption are not much greater than the sum of the linewidths, i.e., when the emission and absorption lines overlap sufficiently.

After resonance absorption, the excited nucleus will decay by either emitting isotropically a γ quantum (as in the primary γ-ray emission of Figure 1) or a conversion electron e^-, preferentially from the K shell. This phenomenon is termed *nuclear resonance fluorescence* and may be used in Mössbauer scattering experiments (surface investigations).

2.2. Recoil Effect

Consider the emission of a γ quantum with energy E_γ from an excited nucleus of mass M in a free atom or molecule (in the gas or liquid phase). The energy of the excited state is E_0 above that of the ground state. If the excited nucleus is assumed to be at rest before the decay, a recoil effect will be imparted to the nucleus upon γ emission, causing the nucleus to move with velocity v in opposite direction to that of the emitted γ-ray (see Fig. 2).

Figure 2. Recoil of momemtum $\vec{p}_n$ and energy E_R imparted to an isolated nucleus upon γ-ray emission

The resulting recoil energy is

$$E_{\mathrm{R}} = \frac{1}{2}Mv^2 = \frac{p_{\mathrm{n}}^2}{2M} \tag{4}$$

Momentum conservation requires that

$$p_\gamma = E_\gamma/c = -p_{\mathrm{n}} \tag{5}$$

where p_γ and p_{n} are the linear momenta of the γ quantum and the recoiled nucleus, respectively, and c is the velocity of light. Hence, the energy of the emitted γ quantum is

$$E_\gamma = E_0 - E_{\mathrm{R}} \approx E_0 \tag{6}$$

Since E_{R} is very small compared to E_0, we may write for the recoil energy (in a nonrelativistic approximation)

$$E_{\mathrm{R}} = \frac{p_{\mathrm{n}}^2}{2M} = \frac{E_\gamma^2}{2Mc^2} \approx \frac{E_0^2}{2Mc^2} \tag{7}$$

For many nuclear transitions $E_{\mathrm{R}} \approx 10^{-2}$–$10^{-3}$ eV. The recoil effect causes the energy of the emitted photon to be decreased by E_{R}, and the emission line appears at an energy $E_0 - E_{\mathrm{R}}$ rather than at E_0. In the absorption process, the γ-ray to be absorbed by a nucleus requires the total energy $E_0 + E_{\mathrm{R}}$ to make up for the transition from the ground to the excited state and the recoil effect, which causes the absorbing nucleus to move in the same direction as the incoming γ-ray photon. As shown schematically in Figure 3 the transition lines for emission and absorption are separated by $2E_{\mathrm{R}}$, which is about 10^6 times larger than the natural line width Γ.

Figure 3. Consequences of the recoil effect caused by γ-ray emission and absorption in isolated nuclei. The transition lines for emission are separated by $2E_{\mathrm{R}} \approx 10^6\,\Gamma$. There is no overlap between emission and absorption lines, and hence no resonant absorption is possible

The condition for overlap of emission and absorption line, i.e., $2E_{\mathrm{R}} \leq \Gamma$, is not fulfilled. Thus, the cross section of nuclear resonant absorption in isolated atoms and molecules in the gaseous and liquid phases is extremely small.

In optical spectroscopy, however, the recoil energy is negligible compared with the linewidth, and the resonance condition is certainly fulfilled for freely emitting and absorbing particles.

Before the discovery of the Mössbauer effect some successful experiments on nuclear resonance absorption in the gas phase had been carried out utilizing the Doppler effect. High velocities were required ($\approx 10^2$ – 10^3 m s^{-1}). This could be achieved either by mounting a source of emitting nuclei on a high speed rotor or by heating the source and the absorber, so that some overlap of the lines could take place.

Rudolf Mössbauer, while working on his Ph. D. Thesis, carried out experiments of this kind with ^{191}Ir. But surprisingly, on lowering the temperature he found an increase in the absorption effect rather than a decrease. Mössbauer was able to explain this unexpected phenomenon, and was awarded the Nobel Prize in 1961 for the observation and correct interpretation of the recoilless nuclear resonance absorption (fluorescence) which is now known as the *Mössbauer effect* and which provided the basis for a powerful technique in solid state research.

2.3. Mössbauer Effect

As explained in Section 2.2, nuclear resonance absorption and fluorescence of γ-rays is not possible for nuclei in freely emitting or absorbing particles. This is different in the solid state. The nuclei are more or less rigidly bound to the lattice. If a γ-ray photon is emitted from the excited nucleus, the concomitant recoil energy may now be assumed to consist of two parts,

$$E_{\mathrm{R}} = E_{\mathrm{tr}} + E_{\mathrm{vib}} \tag{8}$$

E_{tr} refers to the translational energy transferred through linear momentum to the crystallite of mass M. As M is about 10^{20} times larger than the mass of a single atom, the corresponding recoil energy E_{tr} imparted to the crystallite becomes negligible in comparison with γ (Eq. 7).

Most of the recoil energy E_{R} will be dissipated into processes other than linear momentum, i.e., to the lattice vibrational system. E_{vib},

the vibrational energy part, still being of the order of 10^{-3} eV and thus several orders of magnitude smaller than the atom displacement energy (ca. 25 eV) and also much smaller than the characteristic lattice phonon energies (ca. $10^{-1} - 10^{-2}$ eV), is dissipated by heating the nearby lattice surroundings. As a consequence of this phonon creation with frequencies up to w_i, the resulting energy of the emitted γ-ray is

$$E_\gamma = E_0 - \sum_i n\hbar w_i \tag{9}$$

Figure 4. Schematic illustration of the experimental arrangement for recoilless nuclear resonance absorption, and relative transmission of recoilless γ quanta as a function of Doppler velocity

This again would destroy the resonance phenomenon by shifting the emission and absorption lines too far apart from each other on the energy scale. Fortunately, however, the lattice vibrations are quantized, and E_{vib} changes the vibrational energy of the lattice oscillators by integral multiples of the phonon energy, $n\hbar w_i$ ($n = 0, 1, 2, \ldots$). This means that there is a certain probability f that no lattice excitation (energy transfer of $0 \cdot \hbar w_i$, called the zero-phonon process) occurs during the γ-ray emission or absorption process. Mössbauer showed that only to the extent of this probability f of unchanged lattice vibrational states during γ-ray emission and absorption does nuclear resonance absorption become possible. This is termed the *Mössbauer effect*. The probability f is called the recoil-free fraction and denotes the fraction of nuclear transitions which occur without recoil.

The recoil-free fraction in Mössbauer spectroscopy is equivalent to the fraction of X-ray scattering processes without lattice excitation; this fraction of elastic processes in X-ray and neutron diffraction is described by the Debye – Waller factor:

$$f = e^{-k^2 \langle x^2 \rangle} \tag{10}$$

where $\langle x^2 \rangle$ is the mean square amplitude of vibration of the resonant nucleus in the photon propagation direction and $k = 2\pi/\lambda = E_\gamma/(\hbar c)$ is the wavenumber of the γ quantum. The value of f depends on the lattice properties, described by $\langle x^2 \rangle$, and on the photon properties, represented by k^2. The ratio of the mean square displacement and wavelength λ of the photon must be small ($\ll 1$), in order to have a sufficiently high Debye – Waller factor f. Clearly, the Mössbauer effect cannot take place in liquids, where the molecular motion is characterized by unbound $\langle x^2 \rangle$, causing the recoil-free fraction to vanish. The following consequences emerge:

1) f decreases exponentially with k^2, i.e., E_γ^2. The Mössbauer effect can hardly be detected with γ-ray energies above 150 keV.
2) The mean square displacement $\langle x^2 \rangle$ should be small; in other words, the Mössbauer atom should be bound tightly to the crystal lattice. However, crystallinity of the material is not a necessary condition for observation of the Mössbauer effect. The effect is also detectable in amorphous materials, glasses, and in frozen solutions.

3) The recoil-free fraction f is temperature dependent, because $\langle x^2 \rangle$ decreases with decreasing temperature and hence forces f to increase. However, f does not reach unity even at $T = 0$, since $\langle x^2 \rangle \neq 0$ at $T = 0$ because of the quantum-mechanical zero-point motion of the atoms (nuclei). To express f in terms of the usual experimental variables, the mean square amplitude $\langle x^2 \rangle$ is calculated by using lattice dynamic models (e.g., Einstein, Debye) [6], [15].
4) $\langle x^2 \rangle$ and hence f can be anisotropic. As a consequence, a dependence of the intensity of absorption lines on the observation direction in single-crystal experiment may be observed.

3. Mössbauer Experiment

3.1. Doppler Effect

The main components of a Mössbauer spectrometer are the γ-ray source containing the Mössbauer-active nuclides, the absorber (or scatterer), and a detector for low-energy γ radiation (see Fig. 4) plus electronics for automatic recording of the spectrum. The source and the absorber are moved relative to each other (either by moving the source and keeping the absorber fixed or vice versa). The transmitted (scattered) γ quanta are recorded as a function of the relative velocity. In this way, it is possible to trace, stepwise, the absorption line by the emission line utilizing the Doppler effect. A γ quantum which is emitted from the source moving at a velocity v receives a Doppler energy E_{D} modulation such that

$$E_\gamma = E_0 + E_{\mathrm{D}} = E_0 \left(1 + \frac{v}{c}\right) \tag{11}$$

where E_0 is the energy of the γ quantum emitted from the same source at rest and $c$is the velocity of light. This relationship is valid for a moving source, the velocity being positive for the source moving towards the absorber, and negative for moving away from the absorber. Owing to the very narrow linewidth Γ of the resonance line, it is generally sufficient to produce a small Doppler energy change E_{D} of the order of the line width Γ by Doppler shifting the source in order to sweep over the resonance. The Doppler velocities needed in the case of ^{57}Fe spectroscopy are in the range 0 to $\pm\, 10\,\mathrm{mm\,s^{-1}}$, and for most of the other Mössbauer nuclides velocities of less than $\pm\, 100\,\mathrm{mm\,s^{-1}}$ are sufficient.

The Mössbauer spectrum, a plot of the relative transmission as a function of Doppler velocity, shows maximum resonance and therefore minimum relative transmission at relative velocities where emission and absorption lines overlap ideally (Fig. 4). At high positive or negative velocities, the overlap of emission and absorption lines is negligible, the resonance effect being practically zero, i.e., the relative transmission yields the base line.

3.2. Mössbauer Spectrometer

Modern Mössbauer spectrometers generate the spectrum by the velocity-sweep method. The drive system moves the source (or absorber) repeatedly over a range of velocities, while simultaneously counting the γ quanta behind the absorber into synchronized channels.

The essential components of a modern Mössbauer spectrometer, as illustrated in the block-diagram of Figure 5, are the velocity transducer, the wave form generator and synchronizer, the multichannel analyzer, γ-ray detection system, a cryostat or oven for low-temperature and temperature-dependent measurements, a velocity calibration device, the source, the absorber, and a read-out unit.

The source (and in a few cases the absorber) is mounted on the vibrating axis of an electromagnetic transducer (loudspeaker system) [16] which is moved according to a voltage waveform applied to the driving coil of the system. The usual velocity functions are of the triangular, sawtooth, or sinusoidal form. In special cases the source may be moved with a constant velocity.

A function generator produces the desired waveform of the motion. A feedback system (feedback amplifier) operates in such a manner that the actual velocity of the source follows the reference waveform of the function generator with an accuracy better than 0.1 %. Using the triangular waveform one obtains an undistorted spectrum, because the velocity is a linear function of time. In extreme cases, where high velocities are required or the mass to be moved

Figure 5. Block diagram illustrating the principle of a Mössbauer spectrometer

is large, it is preferable to use a sinusoidal waveform. For convenience, this type of spectrum is converted after the measurement into the linear form.

The counts detected behind the absorber are stored in a memory (mostly in the memory of a mutlichannel analyzer containing typically 512 or 1024 channels). Synchronization of the channel number in the memory and the instantaneous velocity of the source (absorber) is achieved by advancing the address of the memory one by one through an external clock which subdivides the period of the waveform into the number of available channels. A start pulse, which coincides with the beginning of the waveform, triggers the multichannel analyzer to start with channel no. 1, which is subsequently advanced by the clock pulses. In this way synchronization is achieved, i.e., during each period of motion a certain channel of the analyzer always corresponds to the same instantaneous velocity of the source. The whole velocity range of interest is scanned many (typically 10 – 50) times per second. As each instantaneous velocity occurs twice during one scan period, the spectrum is registered twice in the memory, where both halves of the memory appear as mirror images, symmetrically about the center of the channel series.

It is essential to have a standard reference line position which other signals can be referred to, particularly in Mössbauer spectroscopy, where different host metals for a particular Mössbauer isotope are often utilized, e.g., ^{57}Co/Cu, ^{57}Co/Pt, ^{57}Co/Rh in case of ^{57}Fe measurements with emitting γ-rays of slightly different energy. The most widely used reference material for velocity calibration in Mössbauer spectroscopy is a natural iron foil of which the six line positions of the magnetic hyperfine split spectrum are accurately known. One uses the distance between the two outermost lines of the iron spectrum as a calibration basis for the measurements of the hyperfine interactions with strengths corresponding to a Doppler velocity region of $0-10\,\mathrm{mm\,s^{-1}}$. This region is suitable for Mössbauer-effect measurements in, e.g., ^{57}Fe, ^{119}Sn, ^{61}Ni, ^{197}Au, and others.

The usual detectors for low-energy γ radiation are thin NaI(Tl) scintillation crystals coupled to a photomultiplier, and gas-filled proportional counters. Considerable improvements in energy resolution can be achieved with solid-state detectors such as the Li-drifted Ge counter.

It is only with low-energy γ emitters, such as the excited state of ^{57}Fe, that the Mössbauer effect can be observed at room temperature and even above. With most Mössbauer isotopes it is necessary to cool the absorber and sometimes also the source to liquid-nitrogen or liquid-helium temperatures to obtain a measurable effect. Apart from these practical requirements

it is often desirable to vary the temperature of the absorber in order, e.g., to obtain information about phase transitions or the electronic state and the molecular symmetry of the compound of interest. Many types of cryostats are nowadays commercially available. The temperature range varies from 1.2 to 300 K in He-bath cryostats and from 6 to 300 K in He-flow cryostats.

A He-bath cryostat equipped with a superconducting magnet can be utilized for Mössbauer investigations of materials in an applied magnetic field. Magnetic fields up to 10 T are common today.

Above room temperature electrical furnaces are used. To minimize the risk of oxidation of the material, a moderate vacuum of about $10^{-2} - 10^{-3}$ mbar is appropriate.

4. Preparation of Mössbauer Source and Absorber

The source for a Mössbauer experiment is a radioactive isotope of reasonable half-life and appropriate nuclear transition energy and excited state lifetime. By radioactive disintegration, the isotope populates a nuclear excited state which decays to the ground state by emitting low-energy γ radiation. Table 1 lists a selection of isotopes which are suitable for practical Mössbauer-effect measurements.

Figure 6. Decay scheme of ^{57}Co

As a typical example, Figure 6 shows the decay scheme of ^{57}Co which populates the 14.4 keV Mössbauer level of ^{57}Fe with a lifetime of $\tau = 140$ ns. The isotope ^{57}Co can be produced in a cyclotron by the nuclear reaction ^{56}Fe(d,n)^{57}Co. The decay of ^{57}Co occurs essentially by electron capture (99.8 %) from the K shell leaving a hole in this shell which is filled from higher shells with emission of a 6.4 keV X-ray. Sources of ^{57}Co are usually prepared by electrochemically depositing the carrier-free isotope on metallic supports and then diffusing it into the metal at high temperatures.

A Mössbauer source should meet the following requirements.

- The emission line should be as narrow and intense as possible, unsplit, and unbroadened
- The recoil-free fraction should be as high as possible
- The source material should be chemically inert during the lifetime of the source and resistant to autoradiolysis
- The host material should not give rise to interfering X-rays, and Compton scattering and photoelectric processes should be insignificant

A uniform absorber with randomly oriented crystallites can be prepared easily by sandwiching the finely ground material between the thin windows of a Perspex holder. In order to obtain undistorted line shapes it is desirable that the absorber is "thin". The natural line width Γ_{nat} of the Mössbauer line having Lorentzian shape [see Section 2.1, Eq. (3)] is determined by the half-life of the excited nuclear state and the Heisenberg uncertainty principle. The experimental line, however, is broadened (Γ_{exp}) for several reasons. The hyperfine fields may have a distribution which is typically observed in amorphous materials and small particles (nano particles). The narrow hyperfine field distribution caused by imperfections and strains in molecular crystals is typically not observed as a line broadening. Dynamic behavior of hyperfine fields lead to line broadenings if the eneries $\hbar\tau_{\mathrm{f}}$ corresponding to the fluctuation time τ_{f} of the fields at the nucleus are of the same order of magnitude as the difference of the hyperfine energies belonging to the field values. The sample thickness gives rise to the so-called thickness broadening which, however, can be taken into account by fitting routines on evaluating the spectra.

Heavy elements in the compound under investigation will scatter and absorb the Mössbauer γ-rays and/or emit photons of similar energy, which are detected along with the Mössbauer photons and lead to a decrease in the signal-to-noise ratio. Mössbauer lines of appropriate intensity can therefore be obtained by

Table 1. Some important isotopes in Mössbauer spectroscopy

Mössbauer isotope	Abundance of stable isotope, %	γ-Ray energy, keV	Half-life of Mössbauer transition, 10^{-9} s	Parent isotope	Half-life of parent isotope
^{57}Fe	2.14	14.4	97.8	^{57}Co	270 d
^{119}Sn	8.58	23.83	17.8	^{119m}Sn	245 d
^{121}Sb	57.25	37.15	3.5	^{121m}Sn	76 y
^{129}I	0 (β^-)	27.77	16.8	^{129}Te	33 d
^{151}Eu	47.82	21.54	9.5	^{151}Sm	90 y
^{197}Au	100	77.35	1.89	^{197}Pt	18 h

decreasing the absorber thickness and increasing the recording time. It is therefore preferable to estimate an optimum absorber thickness for which the measuring time is as short as possible in order to achieve the maximum information from the experiment [17], [18].

5. Hyperfine Interactions

Owing to the narrow linewidth of the Mössbauer nuclear transition (on the order of 10^{-8} eV), the resonance spectrum is extremely sensitive to energy variations of the γ radiation. Interactions between the nucleus and the surrounding electrons with energies comparable to the width of the transition lines manifest themselves in the Mössbauer spectrum. It is the influence of the electronic environment on the emission and absorption lines which determines the hyperfine structure of the spectrum. This interaction of the positively charged nucleus with the electric and magnetic fields caused by the orbital electrons in the region of the nucleus is called hyperfine interaction. This perturbation shifts or splits degenerate nuclear levels.

The Hamiltonian for the nucleus in a solid usually is expressed in a multipole expansion up to the second order

$$H = H_{E_0} + H_{M_1} + H_{E_2} + \dots \tag{12}$$

Higher order terms are negligibly small and cannot be detected by Mössbauer effect measurements. The first term, the so-called monopole interaction, E_0, gives rise to the *isomer shift* δ and shifts the energy levels of both the ground state and the excited state. It originates from the Coulombic interaction between the nucleus and electrons at the nuclear site. The magnetic dipole interaction M_1 removes the degeneracy of the nuclear levels if the nucleus has a magnetic moment. It is commonly known as the magnetic hyperfine interaction and describes the influence of a magnetic field on the nuclear spin (*magnetic splitting*). The third term in Equation (12) represents the electric quadrupole interaction, i.e., the interaction between the nuclear quadrupole moment and an electric field gradient at the nuclear site. The resulting Mössbauer parameter is called *quadrupole splitting*.

The different interactions and the kind of information one can obtain from the respective Mössbauer parameters are summarized in Table 2.

5.1. Isomer Shift

The isomer shift (other names occasionally used are chemical isomer shift or center shift) arises from the fact that the nucleus of an atom possesses a finite volume, and s-electrons have the ability of penetrating the nucleus and spending a fraction of time inside the nuclear region. *p*, *d*, and *f* electrons do not have this ability.

The electric monopole energy of a uniform spherical nucleus with radius and charge in a constant electron charge density $-e|\psi(0)|^2$ is given by

$$H_{E_0} = \frac{2}{5}\pi Z e^2 \left|\psi(0)\right|^2 R^2 \tag{13}$$

The nuclear radii of the ground and excited states, in general, differ by a small amount δR. This results in a gain or loss of Coulombic energy δE of the nucleus when it emits a γ quantum. This energy is transferred to the γ-ray and therefore produces a shift. The same argument holds for the absorption process, so that the total shift δ is expressed by

$$\delta = \frac{4}{5}\pi Z e^2 R^2 (\delta R/R) \left\{ \left|\psi_a(0)\right|^2 - \left|\psi_s(0)\right|^2 \right\} \tag{14}$$

Table 2. The interactions between the nucleus and surrounding electrons, the respective Mössbauer parameters, and the type of information

Type of interaction	Mössbauer parameter	Information
Electric monopole interaction between nucleus and electrons at the nuclear site	Isomer shift δ	a) Oxidation state (nominal valency) of the Mössbauer atom. b) Bonding properties in coordination compounds (covalency effects between central atom/ion and ligands. Delocalization of d-electrons due to back-bonding effects, shielding of *s* electrons by *p* and *d* electrons). c) Electronegativity of ligands.
Electric quadrupole interaction between electric quadrupole moment of the nucleus and electric field gradient at the nuclear site	Quadrupole splitting ΔE_{Q}	a) Molecular symmetry. b) Oxidation state (nominal valency). c) Spin state. d) Bonding properties.
Magnetic dipole interaction between magnetic dipole moment of the nucleus and a magnetic field at the nucleus	Magnetic splitting ΔE_{M}	Magnetic properties (e.g., ferro-, antiferro-, para-, diamagnetism; absolute value and direction of local magnetic fields).

where $\delta R = R_{\mathrm{e}} - R_{\mathrm{g}}$ is the change in nuclear radius on going from the excited (e) to the ground state (g). The subscripts a and s refer to absorber and source, respectively. Figure 7 shows schematically the origin of the isomer shift. From Equation (14) it is clear that the isomer shift is always a relative shift, between absorber and source.

Figure 7. Origin of the isomer shift
A) Electric monopole interaction in source and absorber shifts the nuclear energy levels without affecting the degeneracy; B) Resultant Mössbauer spectrum (schematic)

Therefore, the measured isomer shift is always given with respect to a standard material; this can be the Mössbauer source used in the particular experiment or any conventional absorber material.

The isomer shift is expressed by a nuclear term $\delta R/R$ and an electronic term $\left\{ \left| \psi_{\mathrm{a}}(0) \right|^2 - \left| \psi_{\mathrm{s}}(0) \right|^2 \right\}$, which measures the electron density at the nucleus of an absorber relative to a given source. For a given Mössbauer atom the nuclear factor is constant; the isomer shift is thus exclusively dependent on the difference of the electron densities between absorber and source. For ^{57}Fe $\delta R/R$ is negative, i.e., the nuclear radius in the excited state is smaller than in the ground state; in the case of ^{119}Sn the reverse is true.

The isomer shift can reflect minute changes in the electron density at the nucleus. In a nonrelativistic approximation, the electron density at the nucleus is large only for electrons with zero angular momentum (*s* electrons) and can be approximated by $—\psi(0)—^2$. Hence, the isomer shift of the Mössbauer spectrum is a relative measure of the total *s*-electron density at the nuclear probe in a compound.

The total *s*-electron density of an atom in a chemical compound is the sum of all contributions from the inner (filled) and outer (valence electron) shells. The contribution from the outer electron shells is sensitive to changes in the chemical environment of the element (e.g., change of charge state, change of bonding properties by electron delocalization) and will exert a direct influence on the isomer shift. The valence *s*, *d*, and *f* electrons have only an indirect influence on isomer shift by their shielding effect

on the outer s-electron shells against the positive nuclear charge.

The measurement of the isomer shift gives information on

- The oxidation state (e.g., Fe^{II}, Fe^{III}, Fe^{IV}),
- The spin state (high spin, low spin),
- The bond properties (covalent, ionic),
- The electronegativity of the ligands

of a Mössbauer atom in solid material (coordination compounds, alloys, intermetallic phases, amorphous materials, etc.).

Figure 8 shows approximate ranges of the isomer shifts determined in iron compounds with different oxidation and spin states of the central metal ion.

Figure 8. Approximate ranges of isomer shifts observed in iron compounds (relative to metallic iron). S is the electronic spin quantum number. Note that $(\delta R/R) < 0$ for ^{57}Fe.

It was shown [19] that the electronic density difference on going from the configuration $3d^6$ (Fe^{2+}) to $3d^5$ (Fe^{3+}) essentially originates from changes in the $3s$ shell. The filled $1s$ and $2s$ orbitals remain practically constant for both configurations. The removal of the $3d$ electron leads to an increase in the electron density at the nucleus due to the less effective shielding of the $3s$ electrons from the nuclear charge by the $3d$ electrons in Fe^{3+} as compared with Fe^{2+}. As $\delta R/R$ is negative for ^{57}Fe the isomer shift becomes more negative for Fe^{3+} than for Fe^{2+} (with respect to the same standard). The more or less widespread ranges of the δ values for each oxidation state is a direct consequence of the nature of the chemical bond. The electron distribution in the molecular orbitals is the result of the variable abilities of the ligands to donate electrons to the metal ion by σ bonding and to accept electrons from the metal ion by π bonding.

Correlation diagrams similar to that shown in Figure 8 are available for numerous Mössbauer atoms [20].

5.2. Magnetic Hyperfine Interaction

An atomic nucleus, either in the ground or excited state, with nuclear spin quantum number $I > 0$ possesses a magnetic dipole moment $\vec{\mu}$ and interacts with a magnetic field $\vec{B}$ at the nuclear site. The magnetic field $\vec{B}$ may arise from the electronic environment or from an external magnet. This interaction is called *magnetic dipole interaction* and is described by the Hamiltonian

$$H_{M_1} = -\vec{\mu}\vec{B} = -g_N \mu_N \vec{I}\vec{B} \tag{15}$$

where g_N is the nuclear Landé factor and $\mu_N = e\hbar/2Mc$ (M is the mass of the nucleus) is the nuclear magneton. The magnetic dipole interaction splits a nuclear state $—I\rangle$ into $2I + 1$ equally spaced substates $—I, m_I\rangle$, each of which is characterized by the nuclear magnetic spin quantum number $m_I = -I, -I+1, ..., I$ (nuclear Zeeman effect). The Zeeman energies of the substates are $—I, m_I\rangle$

$$E_M(m_I) = -\mu B M_I/I = -g_N \mu_n B m_I \tag{16}$$

Since the Mössbauer transition in ^{57}Fe is of the magnetic dipole type (M_1), there are only transitions between nuclear sublevels with $\Delta m_I = 0$, ± 1 and $\Delta I = \pm 1$. This selection rule yields only six transitions between the two ground-state sublevels ($I = 1/2$) and the four excited-state sublevels ($I = 3/2$). Figure 9 illustrates the splitting of the nuclear levels, the allowed transitions, and the resulting ^{57}Fe Mössbauer spectrum: a sextet due to the magnetic hyperfine interaction.

Figure 9. Origin of magnetic hyperfine splitting
A) Magnetic dipole interaction in ^{57}Fe in absorber; B) Resultant Mössbauer spectrum (schematic)

The magnetic hyperfine field $\vec{B}$ at the nucleus can originate from its own electron shell ($\vec{B}_{\mathrm{ion}}$), can be generated by paramagnetic ions in the nearby lattice ($\vec{B}_{\mathrm{lat}}$), or can be due to an applied magnetic field ($\vec{B}_{\mathrm{app}}$):

$$\vec{B} = \vec{B}_{\mathrm{ion}} + \vec{B}_{\mathrm{lat}} + \vec{B}_{\mathrm{app}} \tag{17}$$

The dipolar field of the moments of the surrounding paramagnetic ions $\vec{B}_{\mathrm{lat}}$ is a very small contribution.

$\vec{B}_{\mathrm{FC}}$ is the so-called Fermi contact field [21] and represents the most important contribution to the field $\vec{B}_{\mathrm{ion}}$. This field is the direct coupling between the nucleus and the unpaired *s*-electron density at the nucleus [22], [23],

$$\vec{B}_{\mathrm{FC}} = -\frac{16\pi}{3}\mu_B\langle\sum\left(\uparrow\psi_s^2(0) - \downarrow\psi_s^2(0)\right)\rangle \tag{18}$$

where $\uparrow\psi_{\mathrm{s}}^2(0)$ is the spin density at the nucleus of s-electrons with spin parallel to the total spins of the valence d-electrons spin and $\downarrow\psi_{\mathrm{s}}^2(0)$ that with spin antiparallel to the *d*-electron spins.

Since the exchange interaction between the spin-up polarized *d* shell and the spin-up *s* electron is attractive, while that between the spin-up *d* shell and the spin-down *s* electron is repulsive, the radial parts of the two s-electrons distort, one being closer to the nucleus and the other being more distant. As a consequence, the spin-down spin density is enhanced at the nucleus. The direction of the Fermi contact field is antiparallel to this spin, and consequently the Fermi contact field is negative by defintion, which means ant-parallel to the magnetic moments of the *d* electrons.

For high-spin Fe^{III} compounds with electron configuration $3d^5$ (^{6}S), the dipolar field due to its own electrons and the contribution of the orbital momentum to the total field are zero. The Fermi contact term, estimated to be -11 T per unpaired 3*d* electron, dominates over the contributions of the neighboring dipoles and the applied field. In high spin Fe^{II} compounds, however, the negative Fermi contact term is opposed by a positive orbital contribution of almost the same order of magnitude. The positive dipolar contribution is in general quite small. In this case it is impossible to predict the sign of the internal hyperfine field, B_{ion}. This problem can be solved by applying an external magnetic field that aligns the 3*d* moments. Sign and absolute value of the internal field can then be obtained from the vector sum of the applied and the internal field.

5.3. Quadrupole Splitting

The third term in the multipole expansion (Eq 12) describes the *electric quadrupole interaction*. This type of nuclear – electronic interaction is also electrostatic in nature and occurs if the following conditions are fulfilled:

1) The Mössbauer nucleus must possess a measurable electric quadrupole moment *eQ*, which arises from nonspherical nuclear charge distribution leading to spin quantum numbers $I > 1/2$. A measure of the deviation from spherical symmetry is given by the electric quadrupole moment *eQ* which can be calculated by the spatial integral

$$eQ = \int pr^2\left(3cos^2\theta - 1\right)dV \tag{19}$$

where *e* is the proton charge and *p* is the charge density at the spherical coordinates

r and θ. The sign of the nuclear quadrupole moment refers to the shape of the distorted nucleus: Q is negative for a flattened and positive for an elongated nucleus.

2) The electric field at the Mössbauer nucleus must be inhomogeneous, as measured by the electric-field gradient (EFG) $V_{ij} = \partial^2 V/\partial i \partial j$ ($i, j = x, y, z$). This arises from a noncubic charge distribution of the electrons and/or of the neighboring ions around the nucleus.

Figure 10. Origin of the quadrupole splitting in ^{57}Fe
A) electric quadrupole interaction in case of $eQV_{zz} > 0$; B) Resultant Mössbauer spectrum (schematic) with equal intensities as for a powder sample; the inevitable shift of the nuclear levels due to electric monopole interaction giving rise to the isomer shift is also shown

With respect to the principal axes, the EFG tensor is described by only two independent parameters, usually chosen as $V_{zz} = eq$ and $0 \leq \eta = (V_{xx} - V_{yy})/V_{zz} \leq 1$.

The spin Hamiltonian of the nucleus in the principal axes system of the EFG is given by:

$$H_{E_2} = \frac{eQV_{zz}}{4I\,(2I-1)} \times \left\{3\hat{I}_z^2 - I\,(I+1) + \frac{\eta}{2}\left(\hat{I}_+^2 + \hat{I}_-^2\right)\right\} \tag{20}$$

where $\hat{I}_{z,+,-}$ are the usual spin operators.

As an example, the effect of the electric quadrupole interaction in a Mössbauer nucleus with $I = 3/2$ in the excited state and $I = 1/2$ in the ground state, as is the case in ^{57}Fe and ^{119}Sn, is given in Figure 10. The quadrupole interaction gives rise to a doublet with the splitting

$$\Delta Eq = \frac{1}{2}e\left|QV_{zz}\right|\left(1 + \frac{\eta^2}{3}\right)^{\frac{1}{2}} \tag{21}$$

The quadrupole splitting in a Mössbauer spectrum is a highly sensitive probe for the chemical environment that determines the EFG at the nucleus of the Mössbauer atom. In general, there are two fundamental sources which can contribute to the total EFG.

1) Charges on ions surrounding the Mössbauer probe atom in noncubic symmetry give rise to the so-called *lattice contribution*, $(\mathrm{EFG})_{\mathrm{lat}}$ or $V_{zz}{}^{\mathrm{lat}}$ (for axial symmetry).
2) Noncubic distribution of the electrons in the partially filled valence orbitals of the Mössbauer atom generate the *valence contribution*, $(\mathrm{EFG})_{\mathrm{val}}$ or $V_{zz}{}^{\mathrm{val}}$ (for axial symmetry).

According to the different origins (valence/lattice contributions) it is expected that observed quadrupole splittings may reflect information about the electronic structure (oxidation state, spin state), bond properties, and molecular symmetry. As an example the spectra of three iron coordination compounds are shown in Figure 11.

Figure 11. Mössbauer spectra of: a) $FeSO_4 \cdot 7\,H_2O$; b) $K_4[Fe(CN)_6] \cdot 3\,H_2O$; c) $Na_2[Fe(CN)_5(NO)] \cdot 2\,H_2O$

Figure 12. Combined quadrupole and magnetic hyperfine interaction
A) Splitting and shifts; B) Resultant Mössbauer spectrum (schematic)

1) The observed large quadrupole splitting of $\Delta E_Q = 3.4\,\mathrm{mm\,s^{-1}}$ for $FeSO_4 \cdot 7\,H_2O$ essentially arises from the valence contribution $V_{zz}{}^{\mathrm{val}}$. This compound is a typical high-spin compound in which the Fe(II) ion is octahedrally surrounded by six water molecules. This type of ion with a $^5T_{2g}$ ground state is subject to Jahn – Teller distortion, which lifts the degeneracy of the t_{2g} orbitals partly or completely and leads then to a noncubic distribution of the six electrons in the $3d$ shell of the $[Fe(H_2O)_6]^{2+}$ ions. The doubly occupied lowest d_{xy} orbital gives rise to the relatively large quadrupole splitting in the tetragonally compressed $[Fe(H_2O)_6]^{2+}$ octahedron. Further details can be found in reference [12].
2) $K_4[Fe(CN)_6] \cdot 3\,H_2O$ is a typical low-spin Fe^{II} compound. The single-line Mössbauer spectrum results from the absence of a quadrupole interaction due to the cubic charge distribution of the electron configuration $t_{2g}{}^6$ which consequently leads to zero valence contribution $V_{zz}{}^{\mathrm{val}}$ [12]. The lattice contribution $V_{zz}{}^{\mathrm{lat}}$ also vanishes since the $[Fe(CN)_6]^{4-}$ complex ion forms a regular octahedron.
3) The relatively large quadrupole splitting in the case of $Na_2[Fe(CN)_5(NO)] \cdot 2\,H_2O$ is solely due to the fact that the presence of different ligand molecules can no longer form a regular octahedron, as in the case of $[Fe(CN)_6]^{4-}$. The magnitude of the quadrupole splitting is mainly determined by the lattice contribution.

5.4. Combined Quadrupole and Magnetic Hyperfine Interactions

Quite frequently electric quadrupole interactions and magnetic dipole interactions may be present in addition to the electric monopole interactions which are always active. The total Hamiltonian H_{HFS} for the combined electric quadrupole and magnetic dipole interaction cannot be solved analytically in the general case of comparable interaction strengths and arbitrary direction of the magnetic hyperfine field in the PAS of the EFG. In case of a small EFG and large magnetic field, a situation often met, a perturbation treatment may be sufficient. For an axially symmetric EFG with the polar angle ϑ of the

direction of the magnetic field in the PAS of the EFG the eigenvalues of the nuclear sublevels of the $I = 3/2$ state are given by

$$E_{M,Q}(I, M_I) = -g_{\mathrm{N}}\mu_{\mathrm{N}}Bm_I + (-1)^{\left|m_I\right|+\frac{1}{2}}(eQV_{zz}/8)\left(3\cos^2\vartheta - 1\right) \quad (22)$$

We find in the case of ^{57}Fe, which is depicted in Figure 12, that the sublevels —3/2,± 3/2⟩ are shifted by an amount $E_Q(\pm m_I)$ to a higher energy and the sublevels —3/2,± 1/2⟩ are shifted by E_Q to a lower energy, if V_{zz} is positive. These energy shifts by E_Q are reversed if V_{zz} is negative. As a result, the sublevels of the excited state $I = 3/2$ are no longer equally spaced, unless $\cos\vartheta = \sqrt{1/3}$. Combined electric quadrupole and magnetic dipole interactions generally manifest themselves in the Mössbauer spectrum as an asymmetrically split sextet (for $I = 3/2 \longleftrightarrow I = 1/2$ transitions as in ^{57}Fe) as described in Figure 12. As the sublevel spacings and hence the asymmetry of the spectrum is directly correlated with the sign of V_{zz}, one can determine the sign of the EFG of a polycrystalline material from the magnetically split hyperfine spectrum. The effect of a magnetic dipole interaction (applied magnetic field) as a perturbation of the electric quadrupole splitting is described in detail in reference [24].

These three types of hyperfine interactions with the relevant Mössbauer parameters are most important in solid-state research. In addition, one often extracts further helpful information from the temperature and pressure dependence of the Mössbauer parameters, the shape and width of the resonance lines (relaxation phenomena), and the second-order Doppler shift (lattice dynamics).

5.5. Relative Intensities of Resonance Lines

The relative intensities of the lines in a Mössbauer spectrum provide additional information about the orientation of the hyperfine fields with respect to the crystal system in the case of single crystals or partially oriented (textured) samples. For pure magnetic or electric hyperfine fields the intensities are analytical expressions dependent on the direction of the fields with respect to the direction of γ radiation. For powder samples the intensity ratios of pure transitions do not depend on the strength of the fields.

For the case of a magnetically split spectrum of a 3/2 → 1/2 transition the intensity ratios are 3 : 2 : 1 : 1 : 2 : 3 for the hyperfine components of the Zeeman pattern. The corresponding quadrupole spectrum has equal intensities, as mentioned above. For more details the reader is referred to [25], [26].

6. Evaluation of Mössbauer Spectra

The evaluation of a Mössbauer spectrum implies the determination of the physical parameters, the isomer shift, Debye – Waller factor, and electric and magnetic hyperfine fields. When fluctuation times of the hyperfine fields of the order influencing the shape of the spectra are present the fluctuation times themselves may be a parameter of interest.

Fitting of Mössbauer spectra requires the existence of a model for the hyperfine interaction at the Mössbauer nuclei in the material under study. Computer programs are available for a variety of models. The interested reader is referred to the homepage of the Mössbauer community: http://www.kfki.hu/~mixhp.

7. Selected Applications

Since its discovery more than 40 years ago, Mössbauer spectroscopy has become an extremely powerful analytical tool for the investigation of various types of materials. In most cases, only two parameters are needed, i.e., the isomer shift and the quadrupole splitting, to identify a specific sample. In case of magnetically ordered materials, the magnetic dipole interaction is a further helpful parameter for characterization. In the following we shall discuss some applications selected from different research areas.

7.1. Magnetic Materials

As an example we will consider the magnetic ordering in magnetite, Fe_3O_4.

Magnetite is an inverse spinel, with iron atoms occupying interstitial sites in the close-packed arrangement of oxygen atoms. The tetrahedral sites (A) are occupied by ferric cations, and the octahedral sites (B) half by ferric and half by ferrous cations. In the unit cell there are twice as many B sites as A sites. The structural formula can therefore be written: $(Fe^{III})_{tet}[Fe^{II}Fe^{III}]_{oct}O_4$. There is little distortion in the cubic close packing of the oxygen atoms, so that the structure is close to ideal.

Magnetite has a Curie temperature of 840 K. In the magnetically ordered phase the iron atoms on A-sites are antiferromagnetically coupled to those on B sites, and this results in a complete cancelling of the moments of the Fe^{III} ions. Thus, a ferromagnetic moment, originating in the Fe^{II} ions on A sites, remains. On the whole, magnetite shows ferrimagnetic behavior.

Figure 13. Room-temperature Mössbauer spectrum of magnetite; subspectra of lattice sites A and B are indicated by the stick diagram

The statistical distribution of the di- and trivalent ions of iron on equivalent lattice sites (B) explains many unusual properties of magnetite, in particular its extremely high electrical conductivity comparable to that of metals. Investigations have shown that the conductivity is caused by electron and not by ion transport. A fast electron-transfer process (electron hopping) between ferrous and ferric ions on the octahedral B sites takes place [27]. The Mössbauer spectrum of magnetite at room temperature (Fig. 13) confirms this interpretation.

The spectrum consists of two overlapping six-line spectra with internal magnetic fields of 49 and 46 T and a relative area ratio of approximately 1 : 2, which originate from the iron ions on sites A (Fe^{III}) and B (average field of $Fe^{II} + Fe^{III}$). The Mössbauer parameters δ, ΔE_Q, and H_{int} for the sextet stemming from the site-B ions are intermediate between those of oxidic Fe^{II} and Fe^{III} compounds; i.e., the iron ions on lattice site B are a mixed-valent system of Class III in the Robin – Day classification. At ca. 120 K, magnetite shows a so-called Verwey transition. The rate of the electronic hopping between the Fe^{II} and Fe^{III} ions on the lattice B sites slows down such that it becomes slower than the reciprocal of the Mössbauer time window. This causes a significant change in the magnetically split subspectra [28], [29].

Figure 14. Mössbauer spectra of the most important iron-containing corrosion products

7.2. Corrosion Products

Mössbauer spectroscopy of ^{57}Fe has proven to be an extremely powerful tool for the analysis of iron-containing corrosion products on steel and other alloys. Depending on the corrosion conditions a variety of iron oxides and oxyhydroxides may be formed. Mössbauer spectroscopy enables one to differentiate between the various phases on the basis of their different magnetic behavior. Figure 14 illustrates this for six different corrosion products. Fe_3O_4 (magnetite) exhibits two superimposed six-line spectra, as described in Section 7.1.

α-Fe_2O_3 (hematite), γ-Fe_2O_3 (maghemite), and α-FeOOH (goethite) differ in the size of the internal magnetic field, which yields different spacings between corresponding resonance lines. A problem seems to arise with β- and γ-FeOOH, because they have nearly identical Mössbauer parameters at room temperature and cannot be distinguished by their Mössbauer spectra. However, lowering the temperature solves the problem: β-FeOOH appears to be magnetically ordered at 80 K, whereas γ-FeOOH still remains in the paramagnetic state.

Such Mössbauer studies may be carried out in a nondestructive manner and are even possible with highly dispersed particles which are no longer amenable to X-ray diffraction measurements.

7.3. Catalysis

In Figure 15 a series of spectra of the Fe/TiO_2 catalyst system [30] is shown. The top spectrum represents the freshly prepared catalyst; iron is present in the 3+ oxidation state, possibly in the form of finely dispersed oxide or oxyhydroxide on TiO_2. Under a reducing atmosphere (H_2 at 675 K) this iron phase is essentially converted into metallic iron (six line pattern). Some residues of Fe^{II} and Fe^{III} contribute to the spectrum as doublets. Under the conditions of the Fischer – Tropsch synthesis (FTS) at 575 K in CO and H_2 the metallic iron is transformed into the Hägg carbide χ-Fe_5C_2. The unreduced iron is now present as Fe^{II}, which is oxidized to Fe^{III} when the catalyst is exposed to air at ambient temperature. The carbide phase is left unchanged.

Figure 15. ^{57}Fe Mössbauer spectra at room temperature (from top to bottom) of the catalyst system Fe/TiO_2 after different treatments (see text)
Reproduced from *Applied Catalysis* [30]

7.4. Atmospheric Aerosol Samples

Iron is one of the most abundant elements in solid and aqueous atmospheric samples and is usually introduced into the atmosphere as soil dust, fly ash from power plants, exhaust from combustion engines, and from industrial operations. The role of iron in important atmospheric chemical reactions is subject to numerous investigations. Mössbauer spectroscopy proves to be a useful analytical method to determine the iron containing species in the atmosphere. In Figure 16 the result of the Mössbauer analysis [31] of an aerosol sample taken from an air-conditioning system of a building is shown.

Figure 16. 293 K (top) and 8 K (bottom) Mössbauer spectra of the aerosol sample; the decomposition into the spectral components is indicated by the stick bars, where A stands for magnetite (Fe_3O_4), B for hematite (α-Fe_2O_3), C for goethite (α-FeOOH), D for Fe^{II} compounds, and E and F for Fe^{III} compounds

The typically very small crystals of the different components in the aerosol sample give rise to the so-called superparamagnetic (spm) behaviour (cf. Bronger et al. [32] and references therein) resulting in the pronounced resonance doublet for Fe^{3+} compounds in the room-temperature spectrum. The low-temperature spectrum (8 K) revealed that this doublet component mainly originates from superparamagnetic microcrystals of goethite and hematite.

7.5. U.S. One-Dollar Bill

Figure 17 shows the Mössbauer spectrum of a one-dollar bill. For the measurement the note was folded in such a manner that approximately 10 layers of the bill were analyzed. The result of the analysis: the iron-containing pigments of the banknote consist of about 20 wt % of magnetite and 80 wt % of goethite.

Figure 17. ^{57}Fe Mössbauer spectrum of a U.S. one-dollar bill. The different spectral components are marked as: dark gray = magnetite (Fe_3O_4), dashed lines = goethite (α-FeOOH), light gray = spm Fe^{III} component

1. Definitions

The term *meat* means in a narrow sense all skeletal muscles of slaughtered warm-blooded, mostly domesticated animals. During the first days after slaughter the muscles are converted into meat (see Chap. 5) via chemical and physical processes.

Regulations in the Western world, however, summarize under the expression meat, all edible parts of a carcass [1], i.e., muscles with adjacent fat and fatty tissue — in some countries even organs such as liver, kidney, heart, brain and tongue, and also blood. Even if they are summarized under the term "meat", regulations demand different treatment for the various tissues (Chap. 6). Meat in a regulatory sense needs to be intact in structure and available in cuts larger than about 100 g [1]. Meat may only be chilled or frozen to be termed meat. Cutting to small cubes is already a processing step. Also no additions of any kind are permitted in meat. Some states outside the European Union permit the treatment of surfaces with antimicrobial substances (e.g., hypochlorite, ClO_2, H_2O_2, peracetic acid, organic acids) on fresh meat, especially poultry. Also in some states outside the EU the addition of a brine containing various salts (phosphates, $CaCl_2$) at a concentration of about 10 % in order to enhance tenderness and juiciness is permitted with declaration. The product is still called fresh meat.

Meat products and *meat preparations* designate all kinds of meat, either cut in small pieces or comminuted, and all cuts, small and large, covered with herbs or spices and/or treated with additions like salt, brine, or additives.

Skeletal muscles are termed cross-striated muscles, because of their appearance under the microscope (Fig. 1). The filaments (thick and thin) — their spatial arrangement are called myofibers — can slide into each other which causes a contraction (Fig. 2). The repeating unit is called a sarcomere. A sarcomere is about 1.8 – 2.0 µm long and may contract by 0.7 µm. The skeletal muscle contracts by nerve impulses setting Ca^{2+} ions free within the muscle cell. The energy is provided by hydrolysis of ATP to form inorganic phosphate and ADP. The chemical energy is converted into mechanical energy by inducing a series of conformational changes in the "head" of myosin in the thick filament, which binds to actin in the thin filament. After cessation of the nerve impulse, myofibers return into a relaxed state. Myosin is no longer bound to actin [2 – 4].

Figure 1. Micrograph of a cross-striated (skeletal) muscle

Figure 2. Scheme of a sarcomere of a cross-striated muscle

After death the energy is slowly exhausted, ATP disappears by hydrolysis to ADP and AMP and myosin binds permanently to actin. Rigor mortis occurs and the meat gets tough. It must age to become tender and tasty.

2. History

Since several thousand years wild animals have been domesticated. Besides dogs and cats cattle, goats, and sheep were the first animals which were kept by human beings. They produced milk and meat and cattle could be used furthermore for transporting goods or pulling ploughs and carriages. These variable uses demanded different handling. Female animals (cows) gave birth to calves and were used until they were old. Then they were slaughtered and meat, fat, and most organs were eaten. The skin was used for clothes or covers, the bones for tools or poles and the intestines were nearly ideal to keep meat in "containers" and preserve it. Only a few intact male animals (bulls) were kept for reproduction, most males were sterilized and used as steers for transport and pulling. Surplus male calves were slaughtered as unnecessary feed consumers. The obtained veal was tender, the meat of old cows, steers, and bulls was tasty but tougher. Cold storage of meat made it more tender (Chap. 3) but the storage required cooler climates or slaughtering in winter times only. Preservation techniques were developed (Chap. 8), namely drying, salting plus drying, or salting plus smoking. A limited preservation was also achieved by cooking.

The domestication of cows, sheep, and goats was followed by the keeping of chicken and pigs. Contrary to the former, which feed on grass, chicken and pigs were feeding on similar food as humans. Therefore pigs were not used as ubiquitous as cattle. Whereas cattle gave milk and meat for food, pigs produced mainly tasty fat besides meat. Fat of plant origin was available in sufficient quantities only in warmer regions. In moderate climates, such as Central, Western, and Northern Europe, pork fat was the main fat source besides dairy fat until the second half of the 19th century.

3. Composition of Meat

Lean meat is composed of about 75 % water, 22 % protein, 1 – 2 % fat, and about 1 % minerals and vitamins. In a carcass a wide variety of meat cuts with different compositions exist. In pork (Table 1) the fat content varies from 1.5 to 29 %. In beef (Table 2) the variations are nearly as wide. In poultry the maximum fat content is somewhat lower. In all main meat species eaten by humans the mean fat content of fresh meat cuts varies from 7.5 % fat for turkey, to 8.4 % for beef, 9.5 % for chicken, and 10.5 % for pork.

The protein of all meat species has a high biological value. More than 80 % of its amino acids can be used by the human body as the amino acid composition of meat is similar to human requirement [5]. The fat of slaughter animals consists mainly of monounsaturated fatty acids. The contents of unsaturated fat in fatty tissue is shown

* $\bar{\bar{x}}$ = Mean.
** s = Standard deviation.
*** N = number of samples investigated.

in Table 3. Lean meat cuts of all kinds contain around 5 % more unsaturated fatty acids than adipose tissue.

Meat also contains vitamins and trace elements (Table 4). Vitamins of the B group occur in high concentrations. Pork is very high in vitamin B1, 150 g of pork cover the recommended daily intake (RDI) of this vitamin. Lamb is high in vitamins B2 and B12.

Meat is low in sodium but high in potassium. Of the other mineral constituents of meat especially di- and trivalent ions such as iron are important as they are readily absorbed in the human intestines [8]. Due to the very balanced feeding of meat animals in the Western world also the level of trace elements like selenium or manganese is high in meat. Feed supplementation with vitamins, especially the lipophilic vitamins A and E, enhances their content in meat. Meat contains only minute amounts of vitamin C. Liver, however, has vitamin C concentrations of about 25 mg/100 g reaching the vitamin C concentrations of apples.

4. Meat Production and Slaughtering

Cattle, sheep, and goat are usually fed with grass, silage, and hay. Intensive feeding regimes of bulls and steers and many dairy cows require a high protein supplement with their feed. Most of the cattle are not kept in free ranging areas or raised in feedlots. They are kept inside, often due to climatic conditions.

Pigs and chicken are fed mainly with grain. They often receive a protein supplement in form of soybeans and other leguminoses. Most pigs are raised in-house due to climatic requirements. Free-range pigs are the exception. Poultry is also kept inside. Keeping of free-range poultry is rare but increasing.

In former times sheep, chicken, and pigs were slaughtered by cutting the throat. The stronger cattle has to be made unconscious (hammer on the forehead) or exhausted (by bulldogs) before killing.

In the beginning of the 20th century stunning (making unconscious) of animals became legally required in European countries. Captive bolt stunning was introduced, where a steel bolt penetrates the forehead by explosive devices. It

is still the main way of stunning cattle in Europe. Later on stunning by passing an electric current through the brain was developed. Pigs and poultry are stunned today that way. A new technique is stunning by carbon dioxide. The animals are lowered into a CO_2 filled ditch where they turn unconscious. After stunning the animals are killed by debleeding usually by cutting blood vessels in the throat area (called sticking).

After sticking, when more than 95 % of the blood has left the carcass — about five minutes later — the carcasses are either cleaned by hot water or steam or are dehided, respectively defeathered. Then the belly is cut open and viscera are taken out.

After veterinary inspection the carcasses are weighed and graded with respect to meat and fat content (Chap. 11). The chilling process starts usually 30 to 45 min after stunning (Chap. 6). Chilling of cattle and pigs must be so effective that 7 °C are reached throughout the carcass at 24 to 36 h post mortem [9]. In practice pig carcasses are chilled to 7 °C within 16 to 18 h post mortem, cattle within 22 to 30 h. Poultry must be chilled to 4 °C as soon as possible usually within 2 – 6 h after death. Offals must be chilled to 3 °C. The temperatures must not rise above these limits until the carcasses are processed into products or prepared for consumption.

The carcass of cattle weighs about 55 – 65 % of the live weight of the animal [10]. In the case of pigs the carcass weight reaches about 70 %. From the total carcass weight the weight of the bones, tendons, and part of the non-eaten fat, in total about 15 – 20 %, must be deducted in order to obtain the edible portion. This means that about 50 – 60 % of the live weight of an animal is edible meat.

5. Fresh Meat Processing

During slaughter the bloodstream comes to an end. Oxygen and energy rich compounds are no longer transported to the cell and metabolic end products are not removed any longer. All tissues end their steady state metabolism sooner or later. Then they begin to disintegrate. Nerve cells stop their function about 20 min after death. Muscle cells switch from aerobic metabolism with CO_2 and H_2O as end products to an anaerobic breakdown of glycogen, ending with lactic acid [2, 11]. This means that only a small portion of the energy present in the form of carbohydrates (mainly glycogen) can be utilized post mortem. The anaerobic breakdown of glycogen to lactic acid produces three molecules of ATP (by reaction of ADP and phosphate) per glucose unit of glycogen. The aerobic breakdown to CO_2 and H_2O provides about twelve times as much ATP per glucose unit.

In a resting muscle about 5 – 7 mmol ATP per kilogram are available. 50 to 80 mmol glucose units of glycogen present per kilogram muscle can produce 150 to 240 mmol ATP per kilogram post mortem; 100 to 160 mmol lactic acid per kilogram meat are formed as the end product. With a pK_a of 3.9 of lactic acid a pH of about 2 could be reached theoretically in the muscle. But due to the buffering capacity of protein side chains containing free amino groups and other compounds, the pH in meat decreases only to 5.4 – 6.0 under normal conditions from about 7.0 in muscles of a living animal.

Fatty acids cannot be used as a source of chemical energy in post mortem muscle as oxygen is required to form acetyl-CoA. Oxygen is not available post mortem.

Another immediate energy source is creatine phosphate which buffers the ATP concentration in muscle cells. In a resting muscle ATP + creatine form creatine phosphate + ADP. When ATP is needed the reaction proceeds backwards.

Furthermore ADP can be disproportionated enzymatically (catalyzed by adenylate kinase or myokinase) according to

$$2\ \mathrm{ADP} \rightleftarrows \mathrm{ATP} + \mathrm{AMP}$$

ATP returns into the energy cycle, AMP is further metabolized

$$\mathrm{AMP} \rightarrow \mathrm{IMP}\ (\text{inosine monophosphate}) + \mathrm{NH_3}$$

During the early post mortem period energy rich compounds are broken down. Creatine phosphate forms creatine, glycogen is metabolized to lactic acid, ATP is hydrolyzed to ADP and AMP, which is deaminated to IMP. The latter and lactic acid are sensorically very favorable compounds. Both give flavor to the meat. The decrease in pH is of further advantage. It stops or retards the growth of many spoiling or hazardous microorganisms and thus prolongs shelf life.

From a structural point of view, the lack of energy-rich compounds initiates a selfdeteriorating process of the cells. With falling pH the well ordered compartmentation of the cells gets lost. Proteolytic and lipolytic enzymes begin to break down polymeric structures [12]. Especially the well-ordered protein chains in the skeletal muscles (see Chap. 1) are broken down to peptides and finally to amino acids. The loss of the ordered state leads to a tenderization of meat. The activity of proteases varies between muscles but primarily between species.

Tenderness/toughness of meat is determined by the myofibrillar structures of the filaments and the connective tissue [13]. The myofibers are the primary points of action of proteases post mortem. The connective tissue situated outside the muscle cells is attacked only after the cell walls become permeable for proteins. This happens 6 – 10 days post mortem, depending on the species.

Contrary to myofibers the structure of connective tissue depends on age and gender of the animals. Older and male animals develop more cross-links between the protein threads. This makes the connective tissue stronger (tougher).

Meat with strong connective tissue cross-links must age longer for the proteases to become effective. Meat from broilers and pigs — both have not yet reached adult age on slaughter — needs a shorter time of aging then that of cattle. Table 5 shows the minimum time of aging at 3 °C.

Table 5. Time of aging required for tender meat stored at + 3 °C

Species or gender	Time of aging, d
Chicken	1 – 2
Pork	3 – 4
Veal	7 – 8
Heifer meat	13 – 15
Young bull meat	17 – 21

The times in Table 5 are valid for intact meat, intended to be fried or grilled. Meat which is cooked or comminuted can be used much earlier. For Hamburgers (ground beef) meat may be used at two days post mortem.

Besides aging other processing steps influence tenderness. All processes that mechanically destroy structures, such as mincing or pressing, tenderize meat. Also the heating procedure is important. When the temperature rises beyond 40 °C, proteins denature. Fibrous proteins like the ones in myofibers and connective tissue shrink on denaturation [14], which means that the structure gets denser. Myofibrillar proteins start to shrink at around 45 to 50 °C: the meat becomes tougher. At a similar temperature range the heat labile cross-links of connective tissue are hydrolyzed which makes the meat tender. Around 65 °C the connective tissue shrinks. This is the temperature above which the meat gets tough again.

Proper heating is a complicated matter. In veal, pork, or chicken meat the heat-induced changes of toughness are small and a sufficient heating to 70 to 80 °C in order to kill microorganisms is appropriate and acceptable for tenderness. These meats with heat-labile cross-links are tender from around 55 °C (bloody, blue, sanguine) onwards. Heifer meat is most tender around 58 °C, young bull beef at 60 – 62 °C (medium done). Especially young bull beef increases in toughness again on heating above 62 °C up to 80 °C.

6. Processing Techniques

6.1. Chilling of Meat

As mentioned in Chapter 4 meat must be chilled to temperatures low enough to prevent the growth of spoiling or pathogenic microorganisms. Most of the bacteria stop growing below 8 – 10 °C [15]. Thus meat must be chilled to 7 °C as soon as practicable and possible. It is a legal requirement that beef, pork, and sheep meat must be chilled to 7 °C before transport.

Most hygienic rules require that the chilling process of slaughtered carcasses should commence not later than 45 min post mortem. At this time the eviscerated carcasses have been weighted and graded (Chap. 11). The temperature at the surface is below 30 °C but already 1 cm inside the carcass still body temperatures of 38 to 39 °C prevail. If stress has occurred during slaughter, e.g., in the case of pigs, inside temperature may even rise above 40 °C at 45 min post mortem.

Carcasses of cattle, pigs, and sheep are cut along the backbone into two halves. The halves hang on a rail fixed on their hindlegs head down. Cattle and sheep are dehided and the heads are

cut off. Pigs are hanging hide-on with their heads down. The pig carcasses have been scalded and dehaired. Poultry is eviscerated and defeathered, hanging on the rail as whole carcasses with spread legs.

Larger carcasses often pass at first through a freezing tunnel (blast chiller) for 45 to 90 min at temperatures of − 10 to − 20 °C where they are blown with cold air (air speeds up to 3 m/s) in order to remove the heat from the surface as fast as possible. This method has the advantage of reducing the evaporation loss of a carcass (up to 1 % within the chilling down period) and of reducing the time of chilling to 7 °C. Chill room throughput can be enhanced by using a blast chiller in the beginning.

The disadvantages of using a freezing tunnel early post mortem is that a muscle contraction may occur (cold shortening) [13]. Cold shortening takes place in the prerigor state when ATP is present in sufficient concentrations (Fig. 3). That is the case in beef and sheep until 10 h post mortem, in pigs until 4 h, in chicken and turkey until 45 min post mortem. Cold shortened meat gets tough and loses more fluid (drip loss, Fig. 4).

Figure 3. Shortening of beef muscles. Both muscles were excised at 45 min post mortem and cut to the same length, the top sample was chilled for 24 h at 0 °C, the bottom sample to 20 °C for 24 h.

Blast chilling may cause shortening in thinner parts or surface parts of muscles. If the blast chiller is followed by a chiller which keeps the temperatures in the already cold parts below + 10 °C, cold shortening prevails. In chill rooms with moderate chilling the temperatures inside the muscles (up to 40 °C) may warm up the surface above 10 °C and higher and release the muscle contraction. In consequence the temperature fall in a carcass must observe the rule: Fast but not too fast. Table 6 lists the best chilling conditions.

Figure 4. Drip loss of beef and pork muscles in dependence of shortening of sarcomeres

Table 6. Chilling regimes for pig carcasses

Normal chilling	In chiller: air at 0 – 4 °C; slow to medium air movement
Rapid chilling	freezer tunnel at − 10 °C, from 45 min to about 2.5 h post mortem at high air speed (up to 3 m/s and 95 % relative humidity) then 0 – 4 °C in chiller
Shock chilling	freezer tunnel at − 20 °C, from 45 min to 100 min post mortem (air conditions as with rapid chilled) then 0 – 4 °C in chiller

Another disadvantage is that a part of the meat freezes in the blast freezer. Freezing and thawing reduces the quality of meat and enhances drip and evaporation loss.

Instead of using a freezing tunnel, the chilling speed can also be enhanced by chilling with water mist or droplets. Due to the temperature of the water, temperatures of 10 °C and higher are maintained in the prerigor meat. The evaporation loss is minimized. The water vapor or droplets should, however, not be recycled in order to prevent cross contamination.

6.2. Freezing of Meat

Meat can be frozen after it has reached its final pH value. Prerigor meat either contracts before freezing or after thawing and becomes tough.

On freezing ice crystals form. Freezing occurs at first in the extracellular space due to lower concentrations of ions and functional groups of proteins (amino, hydroxy, or carboxyl groups). During slow freezing water moves from the intracellular to the extracellular space. Large ice crystals are formed penetrating the cell wall and enhancing the water migration. Thawing leads then to an enhanced drip loss. Fast freezing results in less migration of water and small ice crystals.

Freezing and thawing must be carried out at similar velocities to reduce drip loss. High velocities are better than lower ones, i.e., freezing of small pieces is advantageous. But in all cases drip loss is higher than in chilled meat. Perforation of cellular structures by ice crystals also eases the penetration of oxygen leading to faster development of off-flavors.

6.3. Heating of Meat and Meat Products

As described in Chapter 5, heating of meat causes structural changes leading to tough or tender meat. The prerequisite to obtain a tender heated piece of meat is the proper aging time (Table 5). Beyond this the heating regime can enhance or lower the tenderness [14]. The heating regime becomes important for meat with a strong connective tissue, i.e., beef, especially from bulls, and meat from older animals like cull cow meat, sow meat, mutton, or meat from hens. In beef the influence is most pronounced (see Chap. 5). Sanguine (bloody) or medium done beef is clearly more tender than well done beef. Cooking of beef above 80 °C and boiling in fluid for a longer period of time tenderizes the meat as the connective gelatinizes.

Heating of meat products fulfills the primary purpose of prolonging shelf life by killing microorganisms. Filling in casings or cans protects against recontamination.

In emulsion-type sausages and cooked hams furthermore a heat stable gel is formed during heating which permits the slicing of the products. Heating to ≥ 65 °C destroys microorganisms and induces gel fromation. Tenderness is not a major problem in comminuted and salted products. Here, the "bite" varies due to salt and additive concentration, the content of lean meat and fat and temperature of heating. The bite is determined by the processor by adjusting the processing conditions.

6.4. Salting and Curing

Salting is defined as the addition of sodium chloride, sometimes contaminated by small amounts of other salts. The first reason of salt addition is the reduction of the water activity (a_w) in order to inhibit or retard the growth of microorganisms. At $a_w < 0.95$ bacteria cannot grow [15], in products with $a_w < 0.7$ also molds stop growing. The second reason is flavor. Curing is the addition of salt plus nitrate or nitrite, respectively. Nitrite inhibits the growth of further microorganisms, e.g., *Clostridium botulinum* or enhances the intensity of the inhibiting action of salt [15]. Furthermore, in the presence of H^+ ions (pH $<$ 6.0) nitrite is converted to nitrous acid

$$NO_2^- + H^+ \rightarrow HNO_2$$

which forms a unstable anhydride

$$2\,HNO_2 \rightleftarrows N_2O_3 + H_2O$$

The anhydride disproportionates into NO and NO_2. NO binds to myoglobin, forming a heat-stable and red NO – myoglobin complex. Usually about 100 – 150 mg/kg nitrite are added with the salt. Due to food law, in several countries nitrite can be added only in a premix with salt, containing about 0.5 % nitrite, the so-called nitrite curing salt. If 2 % of curing salt is added to a product, 100 ppm nitrite are mixed in. If the product is heated, about half of the nitrite is metabolized during heating. The main part is oxidized to nitrate, i.e., nitrite acts additionally as an antioxidant due to scavenging of oxygen. During storage a further part of nitrite disappears as nitrate. Usually a heated meat product at the moment of consumption contains < 30 mg/kg nitrite [16]. In cases of lower pH values and temperatures above 150 °C in a product, nitrous acid forms a NO^+ cation

$$HNO_2 + H^+ \rightleftarrows NO^+ + H_2O$$

which reacts with secondary amines to form stable nitrosamines ($R_2N{-}NO$), that are carcinogenic. Under normal conditions of processing meat into heated meat products the pH is not low enough ($>$ pH 5.6), the temperature of the

heated products is below 100 °C and fresh meat has low concentrations of free amines. Thus, nitrosamines cannot form [17]. In raw meat products, stored for a long period, the content of amines increases and the pH is below 5.6. However, due to low temperatures of storage (ambient and lower) nitrosamines are formed at the limit of detection (ca. 1 µg/kg). Only in fried products (e.g., bacon prepared for breakfast) higher concentrations of nitrosamines occur.

Nitrate itself is ineffective beyond its ionic strength as an antioxidant and as an antimicrobial agent. It must be reduced to nitrite. Reduction takes place in fermented meat products. From the available 300 to 600 mg nitrate per kg, nitrite is slowly formed by special microbial action.

Salting and curing of meat pieces can be done by dry salt addition, immersing into salt brines, or injection of salt brines. During *dry salt curing* the meat pieces are fully covered with salt for several weeks in a chilled room. The salt penetrates slowly into the meat. After that time the surface is cleaned from salt and the product is dried, sometimes cold smoked. After a loss of about 30 % of weight, the product is ready for consumption. This drying period may last up to 12 – 24 months in traditional products. Usually it takes about 1 – 2 months of drying. The *immersion in brine* principally follows the same procedure. By *injection of brine* (20 to 30 %) a concentrated brine solution is pressed in the meat by a multi-needle injection. The following steps are equal to the other procedures. In minced products (all sausages) the salt is added during comminution. It causes swelling and dissolving of myofibrillar proteins which form heat-stable gels in emulsion type products (see Section 8.2.1).

6.5. Use of Additives

According to EU regulations many additives are permitted in meat products [18]. In reality, however, only a limited number of substances are used. The additives are applied primarily for technological reasons. In heated products they shall prevent the cookout of fat and/or water (jelly). Additives are used to improve the cohesion of particles or permit thin slicing of products. Some like nitrite and nitrate retard spoilage and additionally give the products a stable red color which deteriorates only with spoilage. Others lower the pH value of the batter, some are used as flavor enhancers, such as glutamate. Some countries also permit colorants [19].

In some cases the European regulations limit the amounts of additives which may be used. But other additives, especially those with GRAS status, are permitted in "quantum satis" amounts. A few substances are allowed just for the treatment of the surfaces in order to prevent the growth of molds or microorganisms at the outside of casings. One of those is smoke which does not only impart flavor but also contains antibacterial and antimycotic compounds.

Additives may act during processing. For instance diphosphates create a quasi prerigor state of the myofibers (i.e., they separate actin from myosin heads, see Chap. 1). This status enhances gel formation. Due to phosphatase activities in the meat batter diphosphate is hydrolyzed to monophosphate. The latter does not separate actin and myosin. All phosphates, however, sequester di- and trivalent cations and thus prevent the catalytic oxidation of SH side chains of cystein to form S–S bonds of cystin. Early oxidation of SH groups lowers the gel stability of heated batters.

Some high molecular additives like soy, other plant, and milk proteins also strengthen the gel stability as they form a heat-stable network with meat proteins.

6.6. Smoking

Smoke is formed when wood is burned in the presence of insufficient oxygen. Temperatures between 400 and 550 °C should prevail in the wood. Under these conditions pyrolysis of cellulose and lignin occurs [20]. Besides formation of CO_2, CO, water and some volatile compounds (e.g., alkanes) about half of the weight of wood is converted to the actual smoke. The smoke is released into the smoking chamber where sufficient oxygen is available. Secondary pyrolysis products are formed which give the smoke its aromatic flavor. These products include organic acids (e.g., acetic acid), aldehydes (formaldehyde and others), alkohols, phenols, polycyclic aromatic hydrocarbons (PAH)

Figure 5. Smoking chamber
A) Traditional system; B) Modern open system; C) Modern closed system
G = Smoke generator by burning wood; I = Air inlet; F = fan; C = chimney

and other cyclic compounds. Since some of the latter may be carcinogenic, the PAH formation should be prevented or at least minimized. Temperatures around 500 to 600 °C create a minimum of PAH but a high concentration of flavor compounds. In 2005 the EU set MRL for PAH in food [21].

The smoke is introduced into a chamber where meat products hang freely on rails in order to permit the smoke to condense everywhere on the surface. Several types of smoke are applied: *cold smoke* (15 – 25 °C) usually applied on raw hams or raw sausages; *warm smoke* (25 – 50 °C) used for specialty products, e.g., for some emulsion-type product; and *hot smoking* (50 – 90 °C), which is often combined with a cooking process for heated meat products. The time of smoke application varies between 10 and 60 min.

Contrary to former times where burning and smoking was done in the same chamber (Fig. 5 A), nowadays the smoke is produced in a separate burner, entering the smoking chamber through a pipe system (Fig. 5 B and C). On its way the smoke will cool down and substances condense. The smoke may pass through the smoking chamber for a short period of time and leaves through a chimney. In a residential environment an afterburner must burn the smoke to CO_2 and water in order to prevent smell and odor. In modern systems smoke circulates within the chamber for quite some time before it is released into the afterburner. This method saves energy.

Due to carcinogenity of some smoke ingredients some countries limit the concentrations of the most hazardous PAH, benzo[a]pyrene. The concentration is limited by applying fresh smoke only up to 1 µg per kilogram of smoked product (1 ppb) [21]. Modern smoke technologies can easily follow this requirement.

Liquid smoke is a product which has been produced for 20 years. Freshly produced smoke is absorbed in edible oil or water under defined conditions. The liquid smoke or smoke flavoring is analyzed to ensure low or no contents of PAH and applied as an aerosol on the surface of meat products or as an ingredient. Liquid smoke is easy to handle and creates no odor problems in the environment. Furthermore due to the possible analysis prior to application it is low in or free of carcinogenic substances.

6.7. Drying and Other Means of Preservation

The first technologies of meat processing employed were heating and drying. For drying cool and dry climates were necessary. The process could be sped up by drying over a fire. In this way smoking was invented. Drying preserves by lowering the water activity.

Today, drying of meat is done carefully as *freeze drying*. Thin slices (2 – 4 mm thick) of

meat are frozen to − 20 °C and put in a vacuum chamber where they are kept frozen until most of the water has evaporated. Very brittle pieces of meat with 4 – 6 % water are obtained. Due to its brittleness the dried meat is often used in form of dried spherical particles (about 2 cm in diameter) or a coarse powder is made of the end product. The product must be produced in thin sheets or small pieces as the still existing cellular structures, i.e., phospholipid bilayers retard rehydration. Even a short cooking does not permit a rehydration of larger particles.

Another possible means of meat preservation is *irradiation* [22]. It is known from extended experiments that irradiation with 10 kGy is sufficient for preservation. But there is no country which permits the general use of irradiation for meat even if the WHO sees no problems. Only in food for special purposes (for sick or immunosuppressed people) the technology is used also for meat. In some countries the discussion continues if irradiation could be used to inactivate trichinellae.

A technology still rarely but increasingly used is the application of *high pressure*. 3000 to 10 000 bar are applied for about 2 min [23]. With pressures of 3000 – 5000 bar pathogens are inactivated. Lactobacilli survive partially these pressures. The most probable reason for inactivation is that cellular structures are disrupted by pressure application. In practice the vacuum packaged meat is put in a chamber and is surrounded by fluid. The pressure rises in about 2 – 3 min and is released in the same time interval. Due to structural changes meat turns gray and looks like cooked meat. Nitrite-cured meat products, however, keep their red color.

7. Types of Meat Products

Fresh meat is very perishable. Microorganisms can grow easily feeding on the constituents of meat. The reasons are manifold. One is the high water activity ($a_w > 0.99$), which means in simple words that more than 99 % of water are available as solvent and transport medium. Reducing the water activity retards or stops microbial growth. The most obvious way to do this is by drying (Section 6.7). But also higher concentrations of, e.g., salt or sugar lower the water activity (Section 6.4). Another way of preserving is the smoking of meat products as smoke contains antibacterial compounds (Section 6.6). Lowering of pH also retards spoiling microorganisms. Finally heating and subsequently protected storage in casings or cans enhances shelf life (Section 6.3).

Meat products have been invented primarily to prolong shelf life of meat. All aforementioned methods and their combinations are used. The most important meat products include:

1) *Dried Meat.* Thin slices of meat are dried in arid areas like prairies or arctic coasts, this is often preceded by salting. The preparation nowadays takes a few days only. Examples of dried meats are jerky beef (US Indians) or Biltong (South African natives). Dried meat is stored at ambient temperatures.
2) *Raw Meat Products.* Meat pieces are salted in a cool environment (< 15 °C) by covering with salt or immersing in salt brines. This step is followed by drying in dry air and partially by smoking. Examples without smoking include: Parma ham, Jamon Iberico, and Bündner meat. Time of processing is six months to two years, storage at ambient temperature. Examples of smoked products include: Schwarzwälder Schinken (Black Forest ham), Katenrauchschinken, and many other raw hams. Time of processing is one week to several month; the products are stored at ambient temperature.
3) *Raw Sausages*. Slightly frozen meat is comminuted with 2.5 to 3 % salt, spices and fat are added. Often starter cultures are mixed in. The cold batter (below + 5 °C) is filled in casings and incubated at 20 – 25 °C in order to permit the fast growth of the microflora of the starter cultures which lower the pH value. After 1 – 2 days the product is stored at 10 – 15 °C in a dry environment with air-movement. Some of the products are smoked. The product loses water (lowering the water activity) in the dry environment and is stabilized by higher salt concentration (ca. 3 % and above) and a low pH value (pH 5 – 5.5). The product is ready for consumption between one week and six months of processing, depending on the product. Dried products can be stored at ambient temperatures.
4) *Cooked Hams.* Meat pieces are salted as described in item (2). After salting the product is

heated to ca. 65 – 70 °C. The processing time is several days; cooked hams must be stored at < 7 °C.

5) *Cooked Sausages.* Pieces of meat are cooked. After cooking they are partially cut or even minced, spices and salt are added. If liver is added the batter is thoroughly comminuted in a bowl chopper, filled in casings and reheated (*liver sausage*). Afterwards the products are kept under chilling conditions.
   For *blood sausages* the heated pieces of meat are mixed with blood, spices, and salt, filled in casings and reheated. Afterwards the products are kept under chilling conditions. *Aspic products* are obtained if the heated pieces of meat and often vegetables are inserted in dissolved hot gelatin (aspic) solutions with spices, acid and salt and heated in molds. They are stored under chilling conditions.
6) *Emulsion-Type Products*. Raw pieces of meat are comminuted with salt (1.5 – 3 % salt) in a bowl chopper, often additives and spices and about 25 – 35 % of water (usually crushed ice), finally fat meat or fatty tissue (e.g., pork back fat) are added. A further comminution follows until homogeneity is reached (6 to 9 min). The raw batter is filled in casings and heated to between 70 and 100 °C. The formed batter is sliceable at all temperatures. The products are stored at chilling temperatures.
7) *Meat Preparations.* Since the 1960s and 1970s a number of new meat preparations have appeared on the market. They include:
   – Products consisting of raw meat, covered with spices and salt. They are very perishable and must be treated as fresh meat.
   – Meat that is preheated and packed. If it is chilled it must be consumed within a few days.
   – Chilled meat that is minced or comminuted with salt and spices. These raw products should be treated as minced meat and consumed at the day of sale.

8. Manufacturing of Meat Products

8.1. Raw Meat Products

In principle, two kinds of raw meat products exist: Raw pieces of meat which are salted and dried (raw hams) and raw salami type sausages.

For all raw meat products meat with a low bacterial count is needed. This requires a good chilling regime after slaughter during the first 24 h post mortem to ≤ 7 °C and during dissecting of the carcass. Furthermore a low final pH between 5.4 and 5.8 is essential. Proper selection of meat during cutting and a subsequent freezing helps to achieve these conditions. Freezing does not only prevent the growth of microorganisms, by disintegration of cell walls (Section 6.2), it also permits that salt penetrates faster into the meat, lowering the water activity more quickly. Values of $a_w < 0.96$ are required which is reached at about 4.5 % salt in the meat. Fresh meat has a concentration of ions equivalent to 1 % NaCl and a_w values of 0.99.

8.1.1. Raw Hams

In order to prevent microbial growth the raw meat pieces are covered with crystalline salt or immersed in salt brines (8 – 20 % salt) at 3 – 5 °C [24]. The brine can be also injected with a multi-needle injector. By dry salting or immersion in brine the salt ions penetrate slowly into the meat. Depending on the size of the piece it takes several weeks until the NaCl concentration reaches the necessary 4 % NaCl in 1 – 2 cm depth. The temperature remains low until this salt concentration is reached. After taking off the brine the next phase is the equal distribution of salt. During this time the temperature rises slowly. The product is then partially cold smoked and dried at a relative humidity of 80 % and temperatures between 18 and 25 °C. After the drying process has reached the intended state, a further storage at 75 – 80 % relative humidity and about 10 °C is recommended to prevent further drying, growth of molds at the surface, and development of rancidity. The time before raw hams can be sold varies between two weeks for "fresh products" and two years for, e.g., Jamon Iberico.

Smoking of raw hams has nowadays primarily sensorial reasons. But smoking also prevents or at least retards growth of molds. In Mediterranean countries the traditional products have molds growing on the surface as they are not smoked. The molds produce flavor compounds which give Parma ham and others a part of their typical flavor.

Usually not only plain NaCl is added. It may contain nitrite (0.5 %) or nitrate. In some instances only pure salt is used, e.g., in Parma ham. The quality of the product shows that the processing does not necessarily need curing aids.

8.1.2. Raw Sausages

For raw sausages the same raw material requirements exist as for raw hams [24]. Low pH (< 5.8) and low bacterial load are essential. Again frozen meat is appropriate for this kind of sausages. Contrary to raw hams the material is ground or comminuted during the first step of processing. The grinding or comminution starts from meat frozen (− 5 °C) or very well chilled at − 1 °C. This low temperature is required in order to give the fat the necessary hardness. The cutting knives do not smear the fat, they cut through it. In the final product well separated particles of meat and fat are visible on slicing. To the ground material about 3 % curing salt or salt plus nitrate is added during further comminution. Spices, 0.1 – 1.5 % sugar (glucose, fructose, sucrose, lactose, maltose) are added, 50 ppm ascorbate and either glucono-δ-lactone (GdL) or starter cultures are mixed in. The inner anhydride GdL is rapidly hydrolyzed to gluconic acid, lowering the pH value of the mixture from 5.5 to about 4.9 within a few hours. The batter is more stable to many spoiling or pathogenic microorganisms. Starter cultures together with sugars also lower the pH value but act more slowly (in 2 – 3 days, pH < 5.3).

As starter cultures lactobacillae, micrococci, staphylococci, yeasts, or molds are used. The lactobacillae convert the sugars into lactic acid, which lowers the pH value. They themselves also retard or prevent the growth of spoiling or pathogenic microorganisms. Micrococae produce favorable flavor compounds from fats and proteins. Yeasts and molds support the flavor action of micrococci. Some yeasts also require oxygen for metabolism and thus prevent oxidative changes leading to rancidity.

The comminution ends at various degrees of size reduction, in practice reaching from roughly ground meat and fat particles down to a nearly homogeneous batter. End temperatures of − 2 to 4 °C are common.

The batters are filled in casings and subsequently fermented. The temperatures rise up to 25 °C in an atmosphere of 95 % relative humidity. The microorganisms grow and lower the pH. Slowly the relative humidity is reduced to 75 % and the temperature to 15 °C. Lowering of pH and an ongoing loss of water with a reduction of water activity to $a_w < 0.9$ take place within two to four weeks. The water content of the product is lowered from around 55 to 30 %, weight loss reaches up to 30 – 35 %. The salt concentrations increases from ca. 3 to above 4 %. Due to the water loss also protein and fat content increase. The product is ready for sale within two to four weeks. Packaged products may have shelf lives of several months at ambient temperatures, dependent on a_w, pH values, and packaging. Rather fresh and less dried products must be kept under chilling conditions (7 °C and lower).

In roughly ground products due to the drying process and the subsequent increase of salt concentrations, the myofibrillar proteins swell and form a gel at room temperature. The products are sliceable. Finely comminuted products do not form a gel so easily because this is prevented by fat layers between the protein chains. These products are spreadable.

The fat content of raw sausages varies from 30 to 50 %, depending on the amount of fat in the original product and the degree of drying.

8.2. Cooked Products

Cooked meat products constitute the main part of meat products. In central European countries about 65 % of all meat products consumed are heated products.

Three types of cooked products exist:

1) Emulsion-type sausages
2) Cooked (liver, blood) sausages and pate
3) Cooked ham

8.2.1. Emulsion-Type Sausages

Raw pieces of chilled meat are put in a bowl chopper [24]. In the rotating bowl a series of cutting knives comminute the meat. Salt, additives, and spices are added and about one half of the meat weight is added as crushed ice or cold water. The comminution continues until a

homogeneous batter is formed. The temperature is around 5 °C. Variable amounts of fatty tissue (e.g., back fat) are added and comminution continues until about 13 to 15 °C is reached when the batter is again homogeneous. The salt concentration at this stage varies between 1.8 and 3 % depending on the country and the product. The batter is filled in casings or cans and heated; in casings it may be smoked. The product is heated up to 75 °C for so-called "fresh sausages" and up to 120 °C in cans. By addition of salt myofibrillar proteins swell and a part even dissolves in the water. These proteins which have partially hydrophobic areas on their surface surround small fat particles (10 – 100 µm). On heating the proteins form a three-dimensional network, a heat-stable gel. The sausages become sliceable. If nitrite curing salt is added, the nitrite reacts with myoglobin forming nitrosomyoglobin which has an heat-stable red color.

The finely comminuted batter may be mixed with precured pieces of meat, vegetables (mushrooms), or nuts and filled in casings and heated. Usually the fat contents of the finely comminuted batter is around 20 to 25 %.

8.2.2. Cooked Sausages

This group consists of liver and blood sausages, pates, and aspic products.

For *liver sausages* the meat and fat are precooked. The heated material is comminuted, part of the cookout is taken off, the material cools below 60 °C and raw liver is comminuted with spices, herbs and salt and added. The mixture is cooled down to about 35 °C, filled in casings or cans, and reheated up to 75 – 110 °C. Sausages in casings may be smoked during the second heating. The degree of comminution may vary. Liver sausage is a spreadable product as no heat-stable network is formed. Salt is added to achieve hygienic stability and for sensorial reasons. There is no technological need for salt addition as in emulsion-type sausages. Pate production follows the same pattern.

For *blood sausages* the cooked — often precured — meat and fat are cut or coarsely ground, raw blood, spices, salt, and often gelatin are added, the mixture filled in casings and reheated to 75 – 110 °C.

With *aspic products* the same procedure is used. Cooked meat pieces are mixed with spices, salt, organic acids (mainly vinegar), often also with vegetables, and placed in molds with a gelatin solution. The mold is reheated again to 75 – 95 °C.

Neither liver sausages, pates, blood sausages nor aspic products form an heat-stable gel. They may become sliceable in the chilled state.

8.3. Cooked Ham

Whole deboned cuts of hind legs of pigs are brined by injection, smaller pieces of lean meat from all parts of a carcass are put in a so-called tumbler with salt brine and spices. The meat pieces in the tumbler are slowly moved at chill room temperature. During this process the salt penetrates into the myofibrillar structures and lets the proteins swell and partially dissolve. After about 24 h the material is put in casings or molds and heated to 65 – 75 °C. The proteins form a heat-stable network. The cooked ham is sliceable. A traditional product has a yield of 100 – 110 %. Addition of additives which bind water (e.g., nonmeat proteins, agar and other carbohydrate polymers) permit yields of well above 110 %. Some countries call these products *ham and water*. If only lean meat is used, the fat content is below 5 %. Ham and water products may contain less then 2 % fat (more than 98 % fat free).

9. Meat Species Identification

The meat species identification is of general interest for trade and consumers alike. Both want to know which meat species has been used for a meat meal or which species are mixed in a meat product. In various religious and cultural societies some species are not permitted, e.g., pork in Jewish or Moslemic societies, beef in Hinduistic countries. With the upcoming of BSE also the consumers in Europe started to reject beef.

Species identification can be done via detection of

- Proteins specific for the species,
- Fatty acid composition of fats, or
- DNA analysis [25].

Detection of specific proteins can be done by electrophoretic or immunological methods.

Electrophoresis. In electrophoresis polyacrylamide gels (PAGE) proteins are used either in the native or the denatured form (sodium dodecyl sulfate polyacrylamide gel, SDS – PAGE). Denaturation is done with SDS which is absorbed on the surface of the denatured proteins, leading to negative charges on the protein globule due to the sulfate groups. The separation in the SDS – PAGE gel depends on the molecular mass of the proteins. PAGE separates according to the electric charges and the size of the molecule. Proteins may be positively or negatively charged.

In isoelectric focussing (IEF), the proteins are fractionated according to their isoelectric point, by migration along a continuous pH gradient.

All electrophoretic methods work with raw meat extracts or mildly heated meat (< 110 °C). At higher temperatures an intensive denaturation or cleaving of the amino acids chains limit the electrophoretic methods.

Immunological methods with an antigen-antibody interaction open a wider field. Specific antibodies for each species and different denaturation structures permit to detect concentrations of 1 – 2 % of a species in mixtures. Modern enzyme-linked immunosorbent assay (ELISA) tests permit the detection in products heated above 120 °C.

Fatty Acid Analysis. The fatty acid analysis is the most uncertain of all methods. In monogastric species like pigs or poultry the fatty acid composition of fats depends on the fats in the feed. In polygastric species such as cattle or sheep the influence of feed is smaller but still existing. Therefore the source of the material must be known as a prerequisite for the species identification via the fat composition. A species identification on rare fatty acids with more than 20 C-atoms in the chain has been reported [26].

DNA Analysis. In the DNA analysis specific segments of base pairs of a gene can be amplified by polymerase chain reaction (PCR) (→ Polymerase Chain Reaction). A number of species specific primers exist on the market. The PCR test is rather sensitive but not necessarily quantitative. False positive reactions occur already with traces of a species in a mixture. The PCR tests work satisfactorily even above 120 °C up to 130 °C.

10. World Meat Production

Worldwide well above 260×10^6 t of meat were produced in 2004 [27]. Amount of production means produced carcass weight. That is the dressed carcass without eviscera and genitals, without some fat parts and, if customary, without skin but with bones, because the carcasses are usually weighed on the scale at the end of the slaughter process.

The main species used for meat production are pigs. Pork is produced with ca. 101×10^6 t/a. It is followed by poultry (sum of mainly chicken and turkey but also goose and duck) with 77×10^6 t/a. Beef is produced in slightly smaller quantities of around 62×10^6 t/a. Sheep plus goat meat follow with about 12×10^6 t/a [27].

The main *pork* producing area is Asia, especially East Asia, with about 50 % of the worldwide production, followed by Europe with 25 % of the world production. North America contributes 12 % of the annual pork production. Asia also leads in *poultry* production with about one third of the world annual production. North America follows with 25 % annually. Europe produces 17 % of the annual world production. *Beef* production is led by North America with around 27 % of the world production. South America, Asia, and Europe follow each producing between 15 and 19 %. Asia is again the main producer of sheep plus goat meat with about 45 % of the world production. Africa follows with 30 %, Europe with 27 %, and Oceania with 11 %.

All other meat sources are unimportant in comparison. Around 5×10^6 t/a go to all other meats including horse meat, and game.

For many years the meat production has increased annually by 2 – 4 % worldwide. The lowest growth rate is observed in Europe with a surplus meat production. Despite the same economic situation in North America its meat production is slowly growing but more quickly than in Europe. The strongest increase is found in Asia.

11. Meat Grading

One aspect to value a carcass is its dressed weight. The dressed weight consists of lean meat, fat, and bones. The edible parts of a carcass consist of muscular and fatty tissues in various relationships and locations and of some edible offals. The offals vary little in percentage of carcass weight.

The most expensive part of the carcass is the lean meat (muscular tissue). Fat is much less esteemed and bones are cheap byproducts. But the fat in a carcass is often not well separable from the muscular tissue. Muscular tissue may contain thin threads or sheets of fatty tissue. Then the meat is called marbled. The meat content of a carcass must be estimated in order to pay the producer according to the weight and meat content; also customers will buy selected carcasses or carcass parts according to the meat content in order to achieve an optimal use of the meat. Also the proportions of carcass parts are of importance. Large hams of otherwise lean carcasses are welcomed by ham producers.

Due to the unequal distribution of lean meat and fat in a carcass no direct measurement methods of the meat and fat content exist. Until 1980 the meat content was judged by trained graders. This is still the case with cattle carcasses. For pig carcasses instruments were developed in the 1970s which, at certain positions in the back of a carcass, measure, for instance the thickness of back fat and muscular tissue diameter of the loin muscle [28]. The probes insert a needle into the carcass, the tip of the needle having two sets of glass fibers build in. One set of glass fiber emits light, the other set measures the reflection. Light fatty tissue reflects differently than red meat. During insertion a measurement is taken every 0.5 mm and a graph of reflection with the distance is obtained (Fig. 6). An algorithm calculates the meat content of a carcass from the obtained fat and muscles thickness.

Other grading systems measure length, width, and thickness of a carcass part. Furthermore angles (convex and concave forms) of some parts such as hind legs are measured. This is best done with video cameras in three dimensions. A practicable system is being developed at the moment.

Figure 6. Diagram of the pork grading system Fat-o-Meat'er. A measurement value is taken every 0.5 mm. On the right-hand side the reflection of white backfat is depicted, in the center the reflection of the meat in the loin muscle, and on the left-hand side the reflection of fatty and connective tissue between ribs. In the upper picture the reflection of a red, normal muscle is shown; the lower diagram exhibits the higher reflection of pale soft exudative (PSE) meat (courtesy of BRANSCHEID [28]).

Other methods use ultrasound scanning. Ultrasound is reflected at the border of different tissues (fat and muscles). Also the sound velocity is different in different tissue. A number of instruments detect either reflection, velocity of penetration, or both.

X-ray and NMR tomography are also available. In the last years total body electric conductivity (TOBEC) or bioelectric impedance (BIA) have been recommended for meat grading.

All methods of measurement used are indirect methods which are connected with estimation errors. The errors, however, are usually small.

1. Introduction

1.1. Historical Background

In the 1500s THURNEYSSER [1] discovered that violet sap was colored different hues by sulfurous and sulfuric acids. This first indicator was employed over a long period to detect acids. Hydrogen and hydroxide ions acquired their special importance as the dissociation products of water when ARRHENIUS [2] and OSTWALD [3] put forward the ionic theory in the 1880s.

In 1904 FRIEDENTHAL [4] set up the first scale for classifying acids by determining the dissociation constants of weak acids by conductivity measurements and using 14 indicator dyes with color changes at particular hydrogen ion concentrations. He also used this concept for classification of bases. When it became apparent that the dilution of acids or bases did not yield reliable solutions with low hydrogen ion or hydroxide ion concentrations, FRIEDENTHAL, on the advice of PAL SZILY, used the mixtures of salts and acids, that are now referred to as buffer solutions.

FRIEDENTHAL's hydrogen ion concentrations of 10^{-14} to 1 mol/L were awkward to handle. To simplify this problem SØRENSEN [5] suggested taking the negative logarithm of the hydrogen ion concentration. He named it the "hydrogen exponent" and introduced the term pH (*pondus hydrogenii*) for it.

1.2. Buffer Solutions

Today pH values are represented by a series of standard solutions. These standards must maintain their pH values even when contamined with small quantities of acids or bases or when diluted with a little water. *Buffer Solutions* possess this property. Typical buffer solutions consist of mixtures of a weak acid and a salt of this acid with a strong base, or of a weak base and a salt of this base with a strong acid [6].

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.e19_e01

According to the law of mass action (LMA) and ignoring activity coefficients (Section 1.3) it follows for pure acetic acid (HA), for example:

$$c\left(\mathrm{H}^{+}\right) c\left(\mathrm{A}^{-}\right) \approx c(\mathrm{HA}) K_{\mathrm{a}}$$
$$K_{\mathrm{a}} = 10^{-4.74} \mathrm{mol/L} \tag{1.1}$$

If sodium acetate (NaAc) is added, the concentration of acetate ions is equal to that of the added salt C(NaAc) plus that of the dissociated portion of the acetic acid:

$$c\left(\mathrm{A}^{-}\right) = C(\mathrm{NaAc}) + c\left(\mathrm{H}^{+}\right) \tag{1.2}$$

Since $c(\mathrm{H}^{+}) \ll C(\mathrm{NaAc})$, the hydrogen ion concentration can be neglected. Hence

$$c\left(\mathrm{A}^{-}\right) \approx C(\mathrm{NaAc}) \tag{1.3}$$

and since the amount of dissociated acid is low, the actual concentration is approximately equal to the initial concentration C(HA)

$$c(\mathrm{HA}) = C(\mathrm{HA}) \tag{1.4}$$

Then we obtain

$$C\left(\mathrm{H}^{+}\right) C(\mathrm{NaAc}) \approx C(\mathrm{HA}) K_{\mathrm{a}} \textit{ or}$$
$$-\log C\left(\mathrm{H}^{+}\right) \approx \mathrm{pH} \approx -\log K_{\mathrm{a}}$$
$$+\log \frac{C(\mathrm{NaAc})}{C(\mathrm{HA})} \tag{1.5}$$

Equations (1.5) were derived by using approximations that neglect the activity coefficients. This pH is therefore only suitable for approximate calculations. The true pH must be determined experimentally.

The pH values of some buffer solutions are determined exactly and serve as standards for pH measurements (see Section 2.3).

Quantitative reactions of the pH of a buffer solution to external influences are measured in terms of the buffer capacity. The *buffer capacity* is the ration of the differential amount of added substance to the pH change that it causes.

When the additive is a strong acid or base and is measured in gram equivalents n relative to the buffer volume V_{o}, then

$$\beta = \frac{1}{V_0} \left| \frac{\mathrm{d}n}{\mathrm{d}(\mathrm{pH})} \right| \tag{1.6}$$

where β is the *buffer value* in $\mathrm{mol\,L^{-1}\,(pH)^{-1}}$. The second factor in Equation (1.6) is the reciprocal gradient of the titration curve as the titration is commenced. The buffer value is important not only for buffer solutions but also for estimating the ability to control the pH of process solutions. For practical determination of buffer values, see [7].

1.3. Activities

The chemical effectiveness of ions depends not only on their concentration but also on interactions between them. To allow for these deviations it is necessary to multiply the concentrations b [mol/kg] of each substance by its *activity coefficient* γ. The product of concentration and activity coefficient is the *activity* $a = b\,\gamma$. The *law of mass action* (LMA) describes the dissociation of an acid HA correctly as follows:

$$\frac{b\left(\mathrm{A}^{-}\right) \gamma\left(\mathrm{A}^{-}\right) b\left(\mathrm{H}^{+}\right) \gamma\left(\mathrm{H}^{+}\right)}{b(\mathrm{HA})\, \gamma(\mathrm{HA})} = \frac{a\left(\mathrm{A}^{-}\right) a\left(\mathrm{H}^{+}\right)}{a(\mathrm{HA})} \tag{1.7}$$

The correct definition of pH is

$$\mathrm{pH} = -\log \frac{b\left(\mathrm{H}^{+}\right) \gamma\left(\mathrm{H}^{+}\right)}{b^{0}} = -\log \frac{a\left(\mathrm{H}^{+}\right)}{b^{0}} \tag{1.8}$$

where $b^0 = 1$ mol/kg (the units of a).

The condition of electrical neutrality requires that cations and anions are always simultaneously present. Therefore, individual ion activities do not represent any physical reality, and only a geometric *mean activity coefficient* $\gamma_{\pm}$ can be determined directly. For example, the coefficient for sodium chloride is

$$\gamma_{\pm} = \sqrt{\gamma\left(\mathrm{Na}^{+}\right) \gamma\left(\mathrm{Cl}^{-}\right)} \tag{1.9}$$

A large number of mean activity coefficients are tabulated in [8]. They are determined from thermodynamic measurements such as depression of freezing point. In each case the activity coefficient approaches unity in dilute solutions as $b \to 0$.

To obtain an indication of the magnitude of the activities of individual ions, it is necessary to calculate them by theoretical means. The DEBYE–HÜCKEL *theory* of *interionic interaction* [9], developed in 1923, is applicable for ionic strengths in the important range up to 0.1 mol/L. For an ion i

$$\log\gamma = -\frac{Az_i^2 I^{1/2}}{1 + B\text{Å}I^{1/2}} \tag{1.10}$$

where z_i is the charge number and Å is the ionic diameter in Ångstrom. A and B are constants which are only dependent on the relative dielectric constant ε and the temperature T; in water at 25 °C, $A = 0.5108$ and $B = 0.3286$. Values of A and B at other temperatures are tabulated in [10], [11]. However, it is not possible to calculate the diameter of the hydrated ions *Å* accurately; it can only be estimated approximately from crystal data, viscosities, ionic mobilities, etc. The best results available at present are given in [12].

In Equation (1.10) I represents the *ionic strength* expressed in terms of amount-of-substance concentration and is defined as half the sum of the concentrations of all ionic species in solution multiplied by the squares of their charges:

$$I_\mathrm{b} = \frac{1}{2}\sum\left(b_i z_i^2\right) \tag{1.11}$$

At ionic strengths above 1 mol/L the logarithm of the activity coefficient becomes positive, and an additional term is required in Equation (1.10), [8], [13].

The term *ÅB* in Equation (1.10) introduces the greatest amount of uncertainty. According to a convention adoped by BATES and GUGGENHEIM [14] in the case of chloride ions the product *ÅB* is assumed to have the value 1.5 at all temperatures; this is accepted at present as the most likely value. Thus, the DEBYE – HÜCKEL equation becomes

$$\log\gamma\left(\mathrm{Cl}^-\right) = -\frac{AI^{1/2}}{1 + 1.5I^{1/2}} \tag{1.12}$$

It allows the comparison of measured activities.

1.4. Self-Dissociation

The self-dissociation of water is generally written in the simplified form:

$$\mathrm{H_2O} \rightleftharpoons \mathrm{H^+} + \mathrm{OH} \tag{1.13}$$

However, hydrogen ions cannot exist as free protons in any solution. Since it is an elementary particle with a very high charge density, the proton exerts large forces on the surrounding solvent molecules, so that strong electrostatic bonds with the solvent molecule are produced. The first stage in the case of water is the formation of the *oxonium ion*:

$$\mathrm{H^+} + \mathrm{H_2O} \rightleftharpoons \mathrm{H_3O^+} \tag{1.14}$$

The self-dissociation or *autoprotolysis* of water is correctly written as

$$2\,\mathrm{H_2O} \rightleftharpoons \mathrm{H_3O^+} + \mathrm{OH^-} \tag{1.15}$$

The reaction occurs without any measurable treshold and is only limited by the collision frequency [15]. The dissociation constant was first determined by measuring electrical conductivities [16]. The *autoprotolysis constant* of water at 25 °C is:

$$K_\mathrm{aq} = \frac{a\left(\mathrm{H_3O^+}\right)a\left(\mathrm{OH^-}\right)}{a^2\left(\mathrm{H_2O}\right)} = 10^{-15.742}\,\mathrm{mol/L} \tag{1.16}$$

Since the dissociation is only slight, the activity of water [$\log a(\mathrm{H_2O}) = 1.745$] is essentially unchanging; hence, it can be incorporated into the constant. The *ionic product* of water at 25 °C is therefore given in the simplified form by:

$$K_\mathrm{w} = a\left(\mathrm{H^+}\right)a\left(\mathrm{OH^-}\right) = 10^{-13.997}\,(\mathrm{mol/L})^2 \tag{1.17}$$

The consequence is a pH value for pure water of 7.0, and a solution of a strong hydroxide with $a = 1$ mol/L has a pH of 14.

Nonaqueous, but water-like, solvents also self-dissociate in a manner analogous to water. According to the general equation, for HSol as solvent, it follows that

$$2\,\mathrm{HSol} \rightleftharpoons \mathrm{H_2Sol^+} + \mathrm{Sol^-} \tag{1.18}$$

with the autoprotolysis constant

$$K_\mathrm{Sol} = \frac{a\left(\mathrm{H_2Sol^+}\right)a\left(\mathrm{Sol^-}\right)}{a^2\left(\mathrm{HSol}\right)} \tag{1.19}$$

The constant K_Sol depends on the permissivity of the solvent, which ranges from $\varepsilon = 2$ for benzene to $\varepsilon = 182$ for *N*-methylacetamide (water: $\varepsilon = 78$). The range of pH scale in individual solvents is equal to the value of $\mathrm{p}K_\mathrm{Sol}$; this is illustrated graphically in Figure 1. The halfway

point of the scale, where cation and anion concentrations of the solvent are equal, is the neutral point on the pH scale in the solvent concerned. For detailed tables, see [18].

Figure 1. Relative positions of pH scales in different solvents [17]
a) Water; b) Methanol; c) Ethanol; d) 1-Propanol; e) 1-Butanol; f) Isobutyl alcohol; g) Ammonia; h) Hydrazine; i) Acetonitrile; k) Formamide;) l) Formic acid; m) Dimethyl sulfoxide

To compare activities in nonaqueous solutions with those in aqueous solutions we must distinguish between primary and secondary *medium effects*:

$$\log {}^{\mathrm{s}}_{\mathrm{w}}\gamma_i = \log {}^{\mathrm{s}}_{\mathrm{w}}\gamma_i^0 + \log {}^{\mathrm{s}}_{\mathrm{s}}\gamma_i \tag{1.20}$$

where ${}^{\mathrm{s}}_{\mathrm{w}}\gamma_{\mathrm{i}}$ is known as the total medium effect, and ${}^{\mathrm{s}}_{\mathrm{w}}\gamma_{\mathrm{i}}^0$ [19] as the *primary medium effect*. The latter incorporates the activity change which is associated with the change of medium from water to solvent. ${}^{\mathrm{s}}_{\mathrm{s}}\gamma_{\mathrm{i}}^0$ is the *secondary medium effect* or concentration effect of substance *i*, which corresponds to the activity coefficient described above.

1.5. Importance of pH Measurements

The knowledge of the pH value is important in many areas:

- Determination of natural constants, e.g., acid constants
- Chemical industries need pH control in all production stages
- Biotechnology: bacterial growth depends on exact pH control
- One of the first applications was pH control in testing of foodstuffs
- In medicine, pH measurings are part of many diagnoses
- Environmental technology uses pH measurements for monitoring rain and surface waters; pH is the most important parameter.
- Wastewater cannot be regenerated without controlling pH
- The preparation of drinking water is impossible without a pH control

Table 1 lists approximate pH values of some everyday solutions.

Table 1. pH values of everyday solutions [105]

Solution	pH value	Solution	pH value
Gastric juice	ca. 1	Saliva	ca. 6.7
Lemon juice	2.3	Pure water	7.00
Vinegar	3.1	Blood	7.36
Beer	4.3	Sea water	8.3
Sour milk	4.4	Soap suds	8.4
Plum juice	5 – 6	Lime water	12.3
Fresh milk	6.5	Sodium hydroxide $c = (1\ \mathrm{mol/L})$	ca. 14

2. pH Scales

2.1. Indicators

The alteration of the color of dyes under the influence of acids or bases is one of oldest observations in chemistry. The first pH scale, which was set up by FRIEDENTHAL [4], consisted of a table of indicator dyes. For a comprehensive review of modern indicators, see → Indicator Reagents.

2.2. Electrochemical Methods

Practical pH. In industrial chemistry exclusively electrochemical pH measurements are made. A potentiometric cell is used to make a comparison with *standard solutions*. For a single standard [20] we have:

$$\mathrm{pH} = \mathrm{pH\,(S)} - \frac{U - U\,(S)}{k} \text{ with } k = \frac{RT\ln 10}{F} \tag{2.1}$$

where pH(S) is the pH value of the standard solution, U(S) the corresponding voltage of the cell and k the slope of the cell according to the NERNST Law [21]. Values for several temperatures are listed in Table 2.

Table 2. Temperature dependence of the Nernst voltage $k = (RT/F)\ln 10$ [22]

t, °C	k	t, °C	k	t, °C	k
0	54.199	35	61.144	70	68.088
5	55.191	40	62.136	75	69.081
10	56.183	45	63.128	80	70.073
15	57.175	50	64.120	85	71.065
20	58.167	55	65.112	90	72.057
25	59.159	60	66.104	95	73.049
30	60.152	65	67.096		

The Hydrogen Electrode. In 1893 LEBLANC [23] discovered that some metals behave *like hydrogen electrodes* when hydrogen is bubbled over them. Later it was found that platinum metals with hydrogen act as ideal selective electrodes for hydrogen ions. The simple electrode reaction on a platinum metal is

$$H_2 \rightleftharpoons 2\,H^+ + 2\,e^- \tag{2.2}$$

The galvanic potential of the electrode follows the NERNST Law exactly:

$$\varphi_{H_2} = \frac{RT}{F}\ln a\left(H^+\right) - \frac{RT}{2F}\ln P\left(H_2\right) \tag{2.3}$$

For all measurements with the hydrogen electrode the hydrogen pressure must be corrected [24].

When $a(H^+) = 1$ mol/kg and $P(H_2) = 1$ atm, the electrode is called the *standard hydrogen electrode*. Its potential is defined as zero at all temperatures. All potentials relative to this electrode are called *standard potentials*.

The Harned Cell. To obtain exact measurements of hydrogen ion activities, a cell with the hydrogen electrode and a *reference electrode* is required. A silver/silver chloride electrode and an electrolyte containing chloride ions is used. Without a liquid junction, this cell is known as a *Harned cell* (Figure 2). The cell

$$\mathrm{Ag}\,\Big|\,\mathrm{AgCl, HCl}\,\Big|\,\mathrm{H_2, Pt} \tag{2.4}$$

produces a measurable voltage when $P(H_2) = 1$ atm:

$$U = -U^0_{\mathrm{AgCl}} + k\log a\left(Cl^-\right) + k\log a\left(H^+\right) \text{ or} \tag{2.5}$$

$$U = -U^0_{\mathrm{AgCl}} + k\left[\log b\left(H^+\right) + \log\gamma\left(H^+\right) + \log b\left(Cl^-\right) + \log\gamma\left(Cl^-\right)\right] \tag{2.6}$$

Figure 2. Harned cell
a) Ag/AgCl electrode; b) Pt/H_2 electrode; c) Moistening of hydrogen
Courtesy of PTB, Braunschweig

The Ag/AgCl electrode is one of the most widely reference electrodes. It consists of silver metal which is covered with silver chloride. The standard potential U^0_{AgCl} is determined in water [25] and in water – methanol mixtures [26].

2.3. Primary pH Standards

Extrapolation. If the concentration $b(Cl^-)$ [mol/kg] is known, the influence of $\gamma(Cl^-)$ can be estimated. The only certain value is $\gamma(Cl^-) = 1$ at the concentration $b(Cl^-) = 0$. This point is arrived at by extrapolation with stepwise decreasing chloride concentrations. The chloride ion activity must be calculated with the DEBYE – HÜCKEL equation and the BATES – GUGGENHEIM convention, (see Section 1.3) [27], [28]. This calculation allows an extrapolation with a straight line. The result is shown graphically in Figure 3 for a phosphate buffer as an example.

Figure 3. Dependence of p[$a(H^+)\gamma(Cl^-)$] for 0.025 mol/kg phosphate buffer solution on $b(Cl^-)$ [28]

A buffer solution measured in this manner represents at present the best approximation to the hydrogen ion activity defined at

$$\mathrm{pH} = -\log \frac{a\left(\mathrm{H}^+\right)}{m^0} \tag{2.7}$$

Reference Buffers. Some national institutes, (e.g., the *U.S. National Institution of Standards* (NIST) in Washington; the *Physikalisch-Technische Bundesanstalt* (PTB), in Braunschweig, Germany), carry out reference measurements. Substances form tested chemical batches are *certified* and brought on the market as *reference buffer materials* by *accredited* manufacturers [29].

These chemicals are dissolved to form *reference buffer solutions*. Table 3 lists concentrations and pH values of nine *primary standard buffer* solutions. Differences in pH of ± 0.005 between different batches are possible. These solutions represent a pH scale (multipoint scale, DIN 19266) [30].

2.4. Secondary pH Standard Solutions

Differential Potentiometric Cell. The primary pH reference solutions are too expensive for practical use. Commercial buffer solutions are therefore produced by comparison with primary reference buffer solutions. To compare a commercial buffer solution with a primary reference solution, a symmetric cell with two hydrogen electrodes and a liquid junction is used (Figure 4).

Figure 4. Differential potentiometric cell with identical Pt, H_2 electrodes [31]
a) Sintered disk; b) Platinum electrodes; c) Glass tubes; d) Porous glass disks; e) T-tube; f) Bubble flasks; g) Manometer tubes; h) Thermometers; i) Cylindrical funnels for buffer solutions; j, k, l) Stopcocks; m) Outlet tubes

Since the compared solutions are quasi-identical, the liquid junction potential can be neglected. Extensive tests verify that the additional uncertainty is not more than $\Delta\mathrm{pH} = \pm 0.003$ [31]. The two hydrogen electrodes must be exactly isothermal. Measurements should be made at more than one temperature. The uncertainty of secondary reference pH buffer solutions is $\Delta\mathrm{pH} \approx \pm 0.004$.

Technical Buffer Solutions. The primary buffers are relatively dilute solutions with only small buffer values. For technical use higher concentrations with buffer values $\beta > 0.05$ are required. These technical buffers are compared with primary reference buffer solutions, for which the differential cell is not suitable. The measurements are performed with a conventional glass electrode cell (Chap. 3). It is important to use two standard solutions which include the technical buffer. Table 4 lists some examples of buffer solutions recommended by DIN 19267 [7].

Table 3. Examples of primary puffer solutions∗ [30]

Commercial secondary and technical buffers often contain chemical additives to prevent bacterial growth.

Operational pH standards. For preparation of *operational pH standards* (OS) [32] one needs only one reference value pH standard (RVS, one-point scale). This is solution C in Table 4.

An electromotive cell is employed that consists of two Pt | H electrodes and two liquid junctions, e.g.:

$$\mathrm{Pt} \mid \mathrm{H_2}, \mathrm{KCl}, c = 3.5\,\mathrm{mol/kg} \mid\mid \mathrm{RVS}, \mathrm{H_2} \mid \mathrm{Pt} \tag{2.8}$$

Since the hydrogen electrodes work with a theoretical slope, the pH is calculated according to Eq. (2.1):

$$\mathrm{pH} = \mathrm{pH_{RVS}} - \frac{U - U_{\mathrm{RVS}}}{k} \tag{2.9}$$

The *residual diffusion potential* (Section 3.3) is not eliminated. Table 5 lists some of recommended standards.

Nonaqueous Standard Solutions. All standard buffers are valid only for comparison in the same media. Aqueous solutions with extreme concentrations and nonaqueous solutions must be compared with buffers in a like solvent. For this primary and secondary standards with the same solvent as that of the sample are required.

Bates [33] used the Debye – Hückel equation to calculate the activity coefficients of chloride ions in alcohol – water mixtures. He introduced the constants A and B with the dielectric constant of the involved solvent. Since the ionic diameter $\mathring{A}$ in solvents is even less certain

than that in water, BATES also applied here the GUGGENHEIM convention (Section 1.3).

3. Electrode Cells

The following are used as pH indicator electrodes:

1) Hydrogen electrodes
2) Quinhydrone electrodes
3) Glass electrodes
4) Metal electrodes
5) Polymer menbane electrodes
6) pH-selective Field effect transistors (FET)

However, for industrial measurements today, the glass electrode cell is the instrument of choice.

3.1. Glass Electrodes

Historical Background. THOMSON [34] recognized in 1875 that glass is a solid electrolyte in which alkali metal ions can carry electrical current. This led CREMER [35] to propose that this substance might be an ideal semipermeable barrier for univalent cations, and in 1906 he used glass membranes in electrochemical determinations for the first time.

In 1909 HABER and KLEMENSIEWICZ [36] realized the relevance of the NERNST law and began to use the glass electrode for recording titration curves and other purposes [37]. They recognized the importance of a hydrated layer on the surface of the glass and took deliberate steps to produce it.

Construction. A glass electrode of typical design according to DIN 19263 [38] is illustrated in Figure 5. The spherical membrane at the lower end is the actual sensor. It is filled with *internal buffer* and fitted with a lead-off electrode, generally Ag/AgCl electrode. Since the glass membrane has a high electrical resistance, all the potential-bearing components are sensitive to electromagnetic fields and have to be shieled completely, inclusing cables and connectors. This is achieved by using a double-walled shaft containing metal foil.

Figure 5. Standard glass electrode
a) Glass membrane; b) Internal buffer; c) Internal reference electrode; d) Lead connection space; e) Screening; f) Electrode head; g) Electrode lead

The Leached Layer. The surface layers of silicate glasses containing alkali metals undergo an ion-exchange process when they come into contact with water or aqueous solutions. Alkali metal ions from the glass go into solution and are replaced by hydrogen ions. A thin layer containing numerous hydroxyl groups is built up in this manner:

$$\equiv\text{Si–O–Na} + \text{H}_2\text{O} \rightarrow \equiv\text{Si–OH} + \text{Na}^+ + \text{OH}^-$$

The ion-exchange process commences as soon as a new or dry-stored glass electrode comes into contact with water. The exchange is followed by uptake of water to build up a hydrated layer. The hydroxyl groups allow the electrode to function as a sensor for hydrogen ions. However, ion exchange continues in the body of the glass, and so many alkali metal ions appear on the surface in the first few hours that it is only possible to obtain stable readings after ca. 12 h of immersion.

HUBBARD [39] found a conspicuous relationship between the hygroscopicity of glasses and their suitability for pH determination. An excerpt from his results is illustrated graphically in Figure 6.

Figure 6. Relationship between water uptake of eight different soda-lime glasses (Na_2O–CaO–SiO_2 in wt %) and the slope of glass electrodes made of these glasses [39]

BACH and BAUCKE [40] analyzed the surfaces of lithium glass membranes with a depth resolution of 3 – 5 nm by ion bombardement for spectrochemical analysis (IBSCA). The concentration profile in Figure 7 reveals the progress of the ion exchange during the first few hours and at various temperatures. The lithium concentration falls in a quite distinct manner as the surface is approached. Similar concentration profiles were discovered simultaneously by WIKBY [41] and DOBOS [42] on fractional etching with dilute hydrofluoric acid.

Figure 7. Concentration profiles of the outer layers of glass membranes with 25 % (LiO_2) after various conditioning times at 50 °C [40]

16 h the leached layer reaches a steady state
c_g is the lithium concentration in the core of the glass

The degradation of glass does not end with the replacement of alkali metal ions by protons but continues from the surface inwards. With time, electrodes exposed to acidic or neutral solutions aquire a silic-acid-rich residue on their outer surface as a result of irreversible condensation.

$$\equiv\text{SiOH} + \text{HOSi}\equiv \rightarrow \equiv\text{Si–O–Si}\equiv + \text{H}_2\text{O}$$

This layer can be removed by drying, at pH < 3 by alkaline solutions at pH > 12, by hydrofluoric acid at pH < 3, and by mechanical rubbing.

The nonlinear concentration profiles in Figure 7 are the result of the differing diffusion rates of the ions in solution. It is known that in the case of the unchanged glass core, the alkali metal ions are relatively mobile, but protons are less so by a factor of 10^{-4} to 10^{-3} in the absence of incorporated water. BAUCKE and BACH [43] arrived at these orders of magnitude by means of experiments involving ionic migration in strong electric fields. SCHWABE and

DAHMS [44] achieved the same result using radioactively labeled tritium-containing solutions. In the leached layer the mobility of protons along hydrogen bond is much higher.

Membrane Glasses. The hydrogen-ion selectivity of the glass membrane depends on the ion exchange sites being compatible with protons with respect to charge, volume requirement, and coordination number. Membrane glasses should also be able to withstand much chemical and thermal conditions. The search for optimal glasses was complicated by the fact that each change in composition has a simultaneous effect on several properties. The membrane glasses in current use are always compromises for specific applications. There is no universally applicable glass of universal application.

MacInnes Glass (Corning 015) is a pure sodium calcium silicate glass (Na_2O 22, CaO 6, SiO_2 72 wt %) [45]. The first glass membrane suitable for a wide pH range was constructed from it. After its introduction in 1930 it became a standard glass which even today is still used for comparative purposes.

To extend measurements to higher pH levels and reduce the cross-selectivity towards sodium ions, the sodium ions in the membrane were replaced by lithium. The lithium ion is significantly more similar to the hydrogen ion than sodium ion with respect to ionic radius and coordination number.

The oxides of trivalent elements such as boron, aluminum and lanthanum are network formers which lead to glasses of high chemical stability.

According to PERLEY [46] lanthanum oxide can be added to membrane glasses to promote the lifetime at high pH values and temperatures around 100 °C without disadvantageous side effects on hydrogen-ion selectivity.

3.2. Reference Electrodes

The standard hydrogen electrode (Section 2.2) has a fundamental importance as a reference standard, but ready-to-use reference electrodes are preferred for practical determinations. A reference electrode according to DIN 19264 [37] is shown in Figure 8.

Figure 8. Standard reference electrode
a) Electrode head; b) Reference system; c) Reference electrolyte; d) Electrode shaft; e) Filling connection; f) Diaphragm

Table 6. Standard potentials of the most important Ag/AgCl reference electrodes [49], [50]

t, °C	*c* (KCl) at 25 °C			
	1 mol/L	3 mol/L	3.5 mol/L	satd.
0	249.3	224.3	222.1	220.5
10	244.4	217.4	215.2	211.5
20	239.6	210.5	207.6	201.9
25	236.3	207.0	203.7	197.0

35	230.4	199.8	195.4	186.7
40	227.3	196.1	191.2	181.4
50	220.8	188.4	182.4	170.7
60	213.9	180.3	173.5	159.8
70	206.9	172.1	164.5	148.8
80	199.9	163.1	155.6	137.8
90	192.7	153.3	146.8	126.9
95	189.1	148.1	142.5	121.5

The Ag/AgCl reference system is by far most frequently employed because it is simple to prepare and highly reproducible. Potassium chloride or more rarely cesium chloride is used as the electrolyte [48]. The potentials relative to the standard hydrogen electrode are accurately known; they are dependent on the concentration of the electrolyte and the temperature. The

most important reference electrodes with the Ag/AgCl system are summarized in Table 6.

Silver/silver chloride electrodes can be prepared electrolytically or thermally, depending on the properties desired. For temperatures above 80 °C, a tube is filled with a mixture of silver and silver chloride and stoppered with glass wool [51].

The classical *calomel reference electrode* [25] and the *Thalamid electrode* [52] are used more rarely, since their contents are highly toxic.

3.3. Liquid Junctions

In the boundary between two different electrolyte solutions, a potential arises which can be calculated by the *Henderson equation*, described in detail in [53].

Some potentials between the KCl solution of reference electrodes and sample solutions are listed in Table 7. It is not possible to obtain exact values since the structure of the diffusion zone is unknown. The diffusion potential causes the most uncertainty in pH measurements.

Table 7. Diffusion potentials U_d at 25 °C [10]

KCl //	HCl	E_d (mV)	KCl //	NaOH	E_d (mV)
satd.	1 mol/L	− 14.1	satd.	1 mol/L	+ 8.6
satd.	0.1	− 4.6	satd.	0.1	+ 5.4
satd.	0.01	− 3.9			
1 mol/L	1 mol/L	− 27.4	1 mol/L	1 mol/L	+ 18.8
1 mol/L	0.1	− 9.7	1 mol/L	0.1	+ 5.4
1 mol/L	0.01	− 2.8			

The junction between reference electrode and sample solution should always have as low a resistance as possible, but at the same time it should prevent mixing of the two solutions. These two contradictory requirements have led to more or less satisfactory compromises.

The best overview gives a free-flowing reference electrolyte, but in order to minimize the loss of electrolyte it is usually separated from the sample by a *diaphragm* (Fig. 9).

When a reference electrode is transferred from one sample or buffer solution to another, then the first sample that has already diffused into the junction still remains within it initially. The junction is then made up of the following strata: reference electrolyte | old solution | new solution.

Figure 9. Designs of diaphragms
A) Asbestos or platinum wire; B) Porous ceramic; C) Extended porous ceramic; D) Exchangeable porous ceramic; E) Sleeve junction; F) Capillary

The sum of the diffusion potentials of a stratified junction is not equal to the diffusion potential of a direct junction. It takes several minutes for flowing electrolyte to entirely displace the old sample solution. So that for some time the cell exhibits a changing diffusion potential known as a *memory effect* [54]. A permanent outflow of 1 to 10 µL/d is recommended.

Eighty percent of the unexpected difficulties encountered with reference electrodes are attributable to the silver chloride dissolved in the electrolyte. It has been proposed to eliminate the complexed silver ions by an ion barrier in the exit of the tube containing the Ag/AgCl system. This can be a selective exchange resin or a metal which is less noble than silver [55].

The diffusion potential depends on the composition and the concentration of the reference electrolyte; 3.0 and 3,5 mol/L KCl are usually used. However, at temperatures below 0 °C additives are needed to lower the freezing point; an example of a *low-temperature electrolyte* is given in the following [6].

Water	250 mL
NaCl	65 g
Ethylene glycol	750 mL
$a(Cl^-)$	3.0 mol/L
fp	− 30 °C
bp	ca. 180 °C

The chloride ion activity must be verified by measurement with an electrolytic cell.

Diffusion potentials with extreme values do arise, at boundaries between two inmiscible solutions and when a reaction occurs between electrolyte and sample. Then a *double junction* is required with an electrolyte that is miscible with both solutions but does not react with them. That is known as an *electrolyte bridge*. Some examples of bridge electrolytes are listed in Table 8.

Table 8. Some bridge electrolytes recommended for nonaqueous solutions [56]

Solvent	Electrolyte	*c*, mol/L
Acetic acid, anhydrous	$LiClO_4$	0.1
Methanol	LiCl	1.0
Ethanol	LiCl	1.0
Organic solvent/water	$LiClO_4$	0.1

Reference electrodes with liquid electrolytes must always be kept under pressure so that sample solution does not penetrates into the electrode. This is not necessary when the electrolyte is made highly viscous or thixotopic by addition of thickening agents. Water-solouble agents which polymerize in the electrode are best [57]. However, it must taken in consideration that the sample can diffuse into the electrode without any impediment. Therefore, reference electrodes with *solidified electrolytes* have a limited lifetime.

Since all pH measurements are comparisons with standard solutions, the measured result always contains two diffusion potentials, which compensate each other to some extent. Considering this behavior, it would be accurate to write:

$$\Delta U_{\mathrm{d}} = U_{\mathrm{d}} - U_{\mathrm{dS}} \tag{3.1}$$

where ΔU_{d} is the *residual diffusion potential*. Its magnitude depends on the composition of the solutions involved.

The residual diffusion potential can be minimized by using calibration and sample solutions of similar composition. In the case of acids and bases, in particular, calibration and sample solutions should be of similar pH. For this reason, many buffer solutions have been developed for specific purposes.

A new surview of reference electrodes is given in [58].

3.4. Combined Electrodes

Glass and reference electrodes can be combined in a single rod. They are convenient and are used in most cases. Figure 10 illustrates a standard design of a combined electrode for laboratory use. The reference electrolyte is arranged around the glass electrode and serves as an electromagnetic screen. Ceramic and sleeve diaphragms (Fig. 9) are applicable in combined electrode.

Figure 10. Laboratory combination electrode
a) Reference system; b) Filler opening; c) Reference electrolyte; d) Diaphragm; e) Glass membrane; f) Internal buffer; g) Internal electrode system; h) Electrode shaft; i) Electrode head

The concept of a combination electrode is only complete with the incorportion of a resistance thermometer, which is necessary for temperature compensation. The resistance thermometer is usually immersed in the reference electrolyte opposite the reference electrode.

Until the temperature equilibration of reference and internal glass electrode system has occurred, there will be particulary large potential deviations. According to [59], the deviation time can be minimized by constructing a thermally symmetrical electrode system and eliminating convection of the internal buffer. This is achieved by means of a common thermal isolation of the reference and internal electrode sys-

Figure 11. Lower part of a thermally symmetrical combination electrode

tems, as illustrated in Figure 11 (EQUITHAL system).

It is also possible to integrate an electrolyte bridge in the combined electrode (Fig. 12).

3.5. Testing Glass Electrode Cells

The reported *cell zero* pH_0 of a glass electrode only applies for a particular type of reference electrode and can only be tested in conjunction there with. It is the pH value at which the cell voltage is zero. Today's standard is a zero potential of the cell at pH = 7.0.

The correct determination according to IEC 746-2 [22] involves millivolt measurements in several secondary reference buffers which lie within the pH operating range of the glass electrode cell. The temperature should be maintained constant at $25 \pm 0.2\,°C$. The regression line, drawn or computed, gives the true pH_0'.

For cells with small deviation of *k'* a single buffer with a $pH(S_1)$ near pH_0 is enough. The simplified calculation of cell zero is:

$$pH_0\prime = pH\,(S_1) + \frac{U\,(S_1)}{k\prime} \tag{3.2}$$

According to DIN 19263 [38] the deviation of the measured cell zero pH_0' should not differ from the electrochemically defined pH_0 by more than $\Delta pH = \pm 0.5$.

The potential measured at the indicated cell zero is known as the *offset potential*:

$$U_{\text{off}} = k\prime\,(pH_0\prime - pH_0) \tag{3.3}$$

The *slope of a glass electrode cell* is the ratio of ΔU to ΔpH. In theory it should be equal to the NERNST potential *k* (see Section 2.2 and Table 2). The practical response *k'* is usually smaller. It is

obtained from the slope of the straight line Equation (3.2) can also be written

$$\mathrm{pH}_{0}\prime = \mathrm{pH}\,(\mathrm{S}_2) + \frac{U\,(\mathrm{S}_2)}{k\prime} \tag{3.4}$$

For routine measurements a second standard buffer solution S_2 with $pH(S_2)$ is used, such that $pH(S_1)$ and $pH(S_2)$ have a separation of two pH units. The slope is

$$k\prime = \frac{U\,(\mathrm{S}_1) - U\,(\mathrm{S}_2)}{\mathrm{pH}\,(\mathrm{S}_2) - \mathrm{pH}\,(\mathrm{S}_1)} \tag{3.5}$$

Temperature and pH range should be quoted in each case.

Figure 13. Graphical representation of the isotherm intersection
a) 25 °C; b) 65 °C; c) 85 °C

The *temperature coefficient* of the slope is defined as

$$\alpha = \frac{U_{\mathrm{T}_2} - U_{\mathrm{T}_1}}{U_{\mathrm{T}_1}\tau} \tag{3.6}$$

where U_{T_1} is the voltage of the cell at temperature T_1 and U_{T_2} at T_2. $\tau = T_2 - T_1$ is the difference between the two temperatures. The NERNST law gives the theoretical value, which at 25 °C is

$$\alpha\,(25...50^\circ\mathrm{C}) = \frac{1}{\tau}\left(\frac{T_2}{T_1} - 1\right) = 3.354 \times 10^{-3}\mathrm{K}^{-1} \tag{3.7}$$

The theoretical temperature coefficient is the basis of automatic temperature compensation of all pH meters.

The plotted slope following Equation (3.5) is a straight line with $\Delta U/\Delta\mathrm{pH}$ for a given temperature, it is therefore referred to as an *isotherm*. Isotherms at different temperatures have different slopes. The intersection of two or more isotherms is the *isopotential point* with the coordinates $\mathrm{pH}_{\mathrm{is}}$ and U_{is}. It is illustrated for an experimental example in Figure 13.

Using the four equations for the intersection with two standard solutions at two different temperatures gives equation 38.

Here indices 1 and 2 refer to one temperature, and 3 and 4 to the other; indices 1 and 3 refer to the first, and 2 and 4 to the second standard buffer solution. Since the straight lines intersect at a very small angle, the graphical determination of the intersection from two isotherms is less precise than its calculation. Knowledge of U_{is} is necessary for correct temperature compensation.

The *resistance of the glass membrane* at 25 °C rises with use at elevated temperature and with time. It gives information on the usefulness of the electrode. According to DIN 19263 [38] the maximal resistance should be $R_{\mathrm{n}} < 1000\,\mathrm{M\Omega}$ in the operating range.

The practical determination of the operating resistance of glass electrodes is carried out with direct current. However, the higher the potential applied, the more the glass membrane is polarized. The standard IEC 746-2 [22] therefore recommends using only the potential that is set up by the cell itself.

At first the glass electrode cell should be immersed in a solution which differs from the cell zero by $\Delta\mathrm{pH} \approx 2$. The potential is U_1. The second potential is measured after shunting a resistor with $R \approx 1000\,\mathrm{M\Omega}$ over the cell. The membrane resistance is calculated as follows:

$$R_{\mathrm{m}} = R_1\frac{U_1 - U_2}{U_2} \tag{3.9}$$

$$U_{\mathrm{is}} = \frac{(U_3\mathrm{pH}_4 - U_4\mathrm{pH}_3)\,(U_1 - U_2) - (U_1\mathrm{pH}_2 - U_2\mathrm{pH}_1)\,(U_3 - U_4)}{(U_1 - U_2)\,(\mathrm{pH}_4 - \mathrm{pH}_3) - (U_3 - U_4)\,(\mathrm{pH}_2 - \mathrm{pH}_1)} \tag{3.8}$$

According to IEC 746-2 [22] the *response time* required by the display to reach its final value after a sudden change in the sample solution can be divided into phases. These phases, illustrated in Figure 14, are 10 % time T_{10}, rise time T_r (or fall time T_f), and 90 % time T_{90}. It is not necessary to know what form the rate function takes to carry out this classification. To determine the percentage times it is only necessary to know the value of the final reading, the 100 % time.

The equilibrium time is primarily determined by the charge in the uppermost layer. Glass electrodes with thin leached layers react most rapidly. A conditioning time of one hour is optimal in this respect. As the electrode ages, the equilibrium time increases with increasing thickness of the leached layer and increasing membrane resistance. Soiled electrodes and those with old gel layers have response times up to 1000 times longer. Freshly etched electrodes have short equilibrium times. Equilibrium times mostly are shorter in the direction of positive potential change.

3.6. Alternative pH Electrodes

Glass electrodes are almost universal in their application but two alternatives for industrial applications should also be considered.

Enamel electrodes are the only example as yet of the successful reinforcement of a glasslike membrane. A portion of the insulating base enamel is coated with a thin layer of silver, which is then covered by the selective glass enamel [61].

Hydroxide-coated metals are electrodes for hydroxide ions. Since the hydroxide ion activity is related to that of the hydrogen ion by the ionic product of water (see Section 1.4), it is possible to use electrodes of this type to determine the pH. The sum equation can be written

$$Sb(OH)_3 + 3\,H^+ + 3\,e^- \rightarrow Sb + 3\,H_2O$$

However, the hydroxide concerned must not be readily soluble in acids or bases, and for this reason only the metalloids *antimony* and *bismuth* come into question for such electrodes [62].

The robust antimony electrode allows the continuous determination of pH under extreme operating conditions. Antimony electrodes can be continuously cleaned with brushes or corundum stones. The determination of pH under such conditions and in solutions containing hydrofluoric acid are the most important present-day applications of these electrodes.

Antimony and bismuth electrodes have other zero points and greater deviations of slope than glass electrodes. Therefore, they can not be combined with conventional pH meters. To calibrate cells with metalloid electrodes, secondary standard buffer solutions are too dilute. Technical buffers (Section 2.4) are better suited.

4. pH Meters or Transformers

4.1. Input Amplifier

Since the voltage drop resulting from connection of the input amplifier to the pH meter should not to be more than 0.1 % of the cell potential, the *input resistance* must be in the teraohm range, according to DIN 19265 [63] it must be greater than $5 \times 10^{11}\ \Omega$.

Accurate continuous pH determination can only be achieved over extended periods of time if the input voltage is modulated. pH meters transform the signal from the measurement cell into an alternating voltage before amplifying it and then rectify it again after amplification [64]. The alternating power supply feeds both the diode modulator and the synchronous rectifier.

The input amplifier is part of every pH meter. However, it may be advisible to take a second amplifier near the glass electrode as a *preamplifier* to avoid trouble with a long measuring cable.

4.2. Correction Functions

The most important function of pH meters is adjustment to the individual properties of the used electrodes.

The deviation of the cell *zero point*, ΔpH, is adjusted by a suitable compensation voltage. This voltage must be included in the temperature compensation (variable resistor R_2 in Fig. 15).

The *slope* k' in mV/pH is adjusted by varying the negative feedback of the amplifier (variable resistor R_3 in Fig. 15).

Figure 14. Rise curve [22]
T_0 starting time, T_{10} 10 % time, T_{90} 90 % time, T_r rise time, T_f fall time

The *temperature compensation* of a pH meter only takes account of the theoretical temperature coefficient of the NERNST theory (Section 3.5). The sample temperature is either adjusted by hand or automatically determined by means of a resistance thermometer. The resistance thermometer is a Pt-100 (DIN IEC 751) or a Pt-1000. The Pt-1000 is now preferred, since the cable resistance then can be neglected. The temperature compensation is based on the variation in the slope and is corrected with R_4 in Figure 15 in the same way. The output current flows through the temperature compensation resistor at up to 20 mA. To prevent a smaller current can be passed through the resistor and amplifiered in a separate transformation amplifier (not shown in Fig. 15).

Figure 15. Circuit of an analogue pH meter [66]
a) Reference electrode; b) Glass electrode; c) Input amplifier; R_1) Variable resistor for U_{is}; R_2) Variable resistor for ΔpH; R_3 Variable resistor for mV/pH; R_4) Variable resistor for T

The compensation of the *isopotential point* by $\pm$ 100 mV should be possible (R_1 in Fig. 15).

4.3. Output

The output of the pH meter is a current of 0 to 20 mA or 4 to 20 mA at a minimum of 500 Ω. The output ranges are ΔpH = 5 and ΔpH = 10 [63]. In the case of 4 to 20 mA, the 4 mA signal be fed to a digital display.

4.4. Microprocessor-Controlled pH Meters

In digital pH meters equipped with microprocessors the digitized signal can then be processed according to established formulae. The cell signal is amplified as described in Section 4.1 and digitized by an analog/digital converter.

An advantages of these instruments is that none of the calibration buffers must have a value in the neighborhood of the cell zero, so that the calibration points can be chosen at will. The order of presentation of the buffer solutions can also be arbitary.

The digitalized raw data are automatically stored on calibration so that it is not necessary to adjust ΔpH and k'. The values of these variables are only calculated if they are called up for display. If pH values and voltages of two different standard buffers at two temperatures are stored, the isopotential U_{is} is calculated, too.

4.5. Testing pH Meters

To test a pH meter, it is necessary to provide an input that is independent of the conditions of the electrodes and their leads; a so called *pH simulator* is used for this purpose. It produces the same voltage as a pH measurement cell but by purely electronic means. It consists basically of a constant voltage source and a potential divider [22].

When the input is short-circuited the *offset voltage* of a pH meter is directly displayed in the mV range as output U_{A0}. Another output voltage U_{A1} is obtained if the short circuit is replaced by a high-value resistor ($R \approx 1000\,\mathrm{M\Omega}$). The offset or *interference current* is given by:

$$I_{\mathrm{off}} = \frac{U_{A1} - U_{A0}}{R} \tag{4.1}$$

It may amount to only a few picoamperes.

4.6. Self Monitoring

Despite all the progress in pH measurement, glass electrodes with their thin membranes and reference electrodes with open diaphragms are sensitive elements. There are some methods to supervise the electrodes by electronic means. The function can monitored by automatic comparison of the actual pH value with two stored values of the calibration buffer solutions. Unexpected large changes produce an alarm [68].

Membrane break ages can be detected by means of the resulting drop in diminition resistance.

Blocking of the diaphragm and the associated increase in the resistance of the reference electrode is one of the most frequent problems. This is monitored by impedance measurement with alternating current. Interferences result from the capacitance of the electrodes and cables. This can be eliminated with a test circuit containing a capacitance in series. The phase of the test current is analyted by variation of the frequency [70]. It is performed without interrupting the measurement.

Variations in the impedance of the sample solution can disturb the impedance measurement. The electrode impedance is compensated by simultaneous measurements of the sample impedance [72].

4.7. Self Calibration

The pH values of the most important *standard buffers* in the usual temperature range can be stored in a microprocessor-controlled pH meter so that they can be selected afterwards without the risk of operator error. Some manufacturers have gone even further. The instrument itself searches for the used buffer by assuming maximum cell-zero deviations of, say, $\Delta\mathrm{pH} < 0.5$. The instrument monitors the temperature and searches for the correct pH of the buffer solution for the particular temperature [72]. In the case of two-point calibrations the buffer used can also be identified by means of a plausibility test of the calculated electrode data [73].

It is only a small step for a microprocessor controlled pH meter to *self-calibration*. The problem lies primarely with the electrode assembly and the control apparatus (see Section 6.5). The pH meter must be able to carry out the adjustment of $\mathrm{pH}_{0'}$ and k' automatically on receipt of a signal from the control apparatus.

Membrane breakage and diaphragm blockage happen rarely. More frequently, zero point and slope of a glass electrode cause trouble. MELZER [74] proposes a circuit with two glass electrodes, one reference electrode, and two pH meters. The two glass electrodes contain different internal buffers, e.g., with $\mathrm{pH}_{01} = 4.6$ and $\mathrm{pH}_{02} = 7.0$. Then the output with one sample solution with pH is:

$$\begin{aligned} U_1 &= k\prime\,(\mathrm{pH}_{01} - \mathrm{pH}) \\ U_2 &= k\prime\,(\mathrm{pH}_{02} - \mathrm{pH}) \\ U_1 - U_2 &= \Delta U = k\prime\,(\mathrm{pH}_{01} - \mathrm{pH}_{02}) \end{aligned} \tag{4.2}$$

This means that the voltage difference is independent of the sample pH, but it is proportional to the slope, supposed the zero points pH_{01} and pH_{02} remain constant and the slope of both the electrodes are equal. The slope can be measured and compensated on-line if the pH meters are designed properly. The sensor need not be removed from the measured liquid, and a standard buffer is not necessary. Unfortunately on-line determination of zero points is not possible with this method.

Membranes and lead off electrodes should be of the same type. This is best achieved with a

double glass electrode. For the design of a combined electrode for this method, see Figure 16.

Figure 16. Combined double membrane glass electrode
a, b) Glass membranes; c) Reference electrode; d) Diaphragm

5. Analytical Applications

5.1. Calibration of Glass Electrode Cells

Two-Point Calibration. In contrast to Equation (3.5) it is sufficient to use two buffer solutions, at least for routine calibration. Both measurements that make up the calibration must be made at the same temperature, ideally at the temperature at which the samples will be investigated. If there is a manually adjusted temperature compensation this should initially be set to the temperature of calibration. The temperature should be maintained within at most ± 0.5 K of the calibration temperature.

The zero point is adjusted by using the first buffer that is as close as possible to the reported cell zero. This step is expressed in Figure 17 in terms of a parallel displacement of the calibration line along the abscisa by $\Delta pH = pH_0' - pH_0$. The pH of the second buffer solution should differ from pH_0 by at least 2 pH. It is used to adjust the slope of the straight line k' (in mV/pH). The two calibration solutions should bracket the desired measurement range. The adjustment of the slope also affects the adjustment of the zero point. If the pH_1 of the first buffer differs from pH_0' by more than 0.5, then the calibration must be repeated.

Figure 17. Correction of zero point and slope
a) True relationship between pH and cell voltage; b) Relationship in pH meter after adjustment of ΔpH; c) Variation after adjustment of k' in mV/pH
pH_0 quoted cell zero, $pH_{0'}$ actual cell zero

The standard deviation of the two-point calibration amounts to $\Delta pH \approx 0.02$.

Multipoint Calibration. If more than two calibration points are plotted they will not lie exactly on a straight line. DIN 19268 [76] and Baucke et al. [77] therefore recommend *multipoint calibration* with three or four calibration solutions in cases where high accuracy is required. For this the millivolt range of the pH meter is used. Each reading should be made when the drift has settled to less than 0.1 mV/10 min. This can mean that waiting times of up to 30 min can be required for each determination. The most probable straight line is than calculated from the results by the method of least squares [78], [79].

Uncertainity of pH Measurement. In this section ΔpH values of 0.01 to 0.02 were quoted, depending on the calibration method. This is valid only under pure laboratory conditions. For industrial environments McMillan [80] esti-

mated uncertainities of $\Delta pH \approx \pm 0.25$. In case of multipoint calibration it is possible to calculate the mean error [78].

5.2. pH Measurement in Water Analysis

The recommendations of DIN 38404-5 [81] and ISO 10523 [82] are applicable to drinking, process, spring, and surface water with conductivities of $\sigma > 100\,\mu S/cm$. Conventional sampling techniques and standard buffer calibrations can be used. According to the *German drinking water law* (Trinkwasserverordnung) [83] the pH of ready-to-use drinking water must lie between 6.5 and 9.5. If the public mains contain asbestos cement then in addition the pH must not deviate by more than $\Delta pH = 0.2$ below the pH of *calcium carbonate saturation* [84].

Difficulties are often met in measuring the pH of samples with a low conductivity. This is particulary true of high-purity water, produced by distillation, deionization, or dialysis, and rainwater. For the last-mentioned see [85].

Galster [86] has made some effective recommendations for completely desalted water on the basis of theoretical considerations and practical experience: It is preferable to use a reference electrolyte containing not more than $c(KCl) = 1$ mol/L and a sleeve as-liquid junction (Section 3.3). Since electrostatic charges take some time to flow away it is recommended to provide the sample solution with a shield and a large-surface ground.

The extremely small buffer value means that the pH of a sample drops rapidly as carbon dioxide is absorbed from the air.

The response of glass and reference electrodes have a hysteresis effect when they are changed from usual buffer solutions into a low-ionic water. It is better to employ diluted standard buffers [87]. Technical buffers should not be used.

In wastewater the danger of contamination of the electrodes is greater and the accuracy that is required is lower. For this reason it is best to use reference electrodes with extended or exchageable diaphragms (Section 3.3). Reference electrolytes with polymer-immobilized reference electrodes and an open junction are permitted [88].

5.3. pH Measurement in Concentrated Solutions

Nonelectrolytes. It has long been known that in concentrated solutions of sugars low measured pH values are too high and high measured pH values are too low when compared with calculated values. A solution containing 26 wt % sucrose exhibits an apparent slope of only 53.2 mV/pH between pH 3 and 12 and the diffusion potential is elevated [89], [90]. This effect is the result of changes in the fine structure of water caused by the presence of the sugar molecules. Highly concentrated solutions can no longer be regarded as purely aqueous, so that it is necessary to take into account medium effects (Section 1.4).

Electrolytes. Schwabe [91] has made extensive investigations of pH displacement in concentrated solutions of electrolytes. The lowering of pH of a acid solution by the addition of electrolytes follows by the enlargement of ionic strength. The diffusion potential in concentrated solutions is lower than calculated as in Section 3.3, because the rates of migration of ions are diminished at concentrations $b > 1$ mol/kg. Conventional glass electrodes are suitable for such determinations. Hydrogen and glass electrodes agree closely with each other even at very high concentrations and at temperatures above 100 °C [92].

Strong Acids. The major problem of pH determination in strong acids is the magnitude of the diffusion potential. The diffusion potential can be stabilized by interposing an electrolyte bridge between reference electrode and sample containing sample solution (see Section 3.3).

The cross-sensitivity of glass electrodes towards anions was mentioned with in Section 3.5, the "acid error" only appears after several hours; therefore, it is recommended that individual measurement be made rapidly.

Strong Bases. Potassium hydroxide solution allows the production of solutions with $pH > 14$. However, in highly concentrated solutions a much of the water is required for hydration, so that the *activity of water* can drop. The activity

coefficient of hydroxide ions $\gamma(OH^-)$ increases to much as 30 in concentrated hydroxide solutions. As the hydroxide ion concentration increases, the pH increases in the following way:

$$\mathrm{pH} = \mathrm{p}k_a - \log a\,(\mathrm{H_2}O) + \log b\,(\mathrm{OH^-}) + \log\gamma\,(\mathrm{OH^-}) \quad (5.1)$$

This means that a concentrated solution of, e.g., potassium hydroxide having a concentration of 17.5 mol/kg has a theoretical pH of 17.65 [93].

However the cross-sensivity of the glass electrode towards cations is a much greater problem (Section 3.5).

Even the best glass electrode must be expected to deviate greatly above pH 14.

5.4. Suspension Effects

Potentiometric determinations in suspensions, sludges, and particulary in soils can exhibit unexpectedly large errors. This effect is also known as the *Wiegner – Pallmann effect* [94], [95]. Two independent phenomena are involved [96].

1) The *type 1 suspension effect* influencing the sensor electrode
2) The *type 2 suspension effect* influencing the reference electrode on account of an anomalous diffusion potential.

The type 1 suspension effect was initially demonstrated in investigations on suspensions of γ-Al_2O_3 in pure water (Fig. 18). The apparent pH measured in the suspension was about 0.4 pH units higher than in the clear supernatant. Aluminum oxide and some other substances absorb hydrogen ions from acid solutions and hydroxide ions from basic solutions and thus act as a suspended buffers.

The type 2 suspension effect occurs more frequently than type 1 and its magnitude is up to ten times higher. It is especially to be observed when substances possess ion-exchange properties. Figure 18II demonstrates the effect schematically.

The relatively immobile suspended particles, which are electrically charged on account of the zeta potential, reduce the mobility of ions with like charge and hence have an influence on the magnitude of the diffusion potential as soon as they come into contact with reference electrolyte [98]. The effect also must be considered in suspensions of microbiological fermenters [99].

Figure 18. Suspension effects
I) Type 1 suspension effect: the diagrams indicate the measured pH as a function of the position of the reference and glass electrodes in the clear supernatant and in the sediment
A) pH = 8.56; B) pH = 9.57; C) pH = 8.91; D) pH = 8.92
II) Type 2 suspension effect: the diagrams indicate the measured pH as a function of the position of the reference and glass electrodes in the clear supernatant and in the sediment
A) pH = 6.0; B) pH = 2.0; C) U = 0 mV; D) U = 240 mV
a) Suspension solution; b) Suspension

The type 2 suspension effect is dependent on the composition of the reference electrolyte. It can reduced by including an electrolyte bridge with an electrolyte consisting of a clear solution obtained by filtration or centrifugation of the sample.

5.5. pH Measurement in Nonaqueous Solvents

Liquid ammonia is the best investigated nonaqueous inorganic solvent. The use of liquid ammonia as a solvent for the titration of very weak acids has been suggested [100]. The glass electrode can be used for determinations below the boiling point of liquid ammonia (– 33.38 °C). For this purpose a high-conductivity membrane

glass is combined with a low-temperature internal buffer. The authors used a cell in which liquid ammonia is also the solvent for the reference electrolyte. The used glass electrode has a mixed solvent with methanol as internal buffer and is conditioned as usual in aqueous solution and immersed in liquid ammonia after it has been dried briefly.

Cruse [101] has provided a comprehensive description of the determination of pH in organic solvents. Figure 1 shows the approximative relative positions of the pH scales in various solvents [17]. However, it is not possible to make direct comparisons of pH values on different scales. The correct procedure would be to set up a pH scale with primary pH standards for each solvent, as described in Section 2.4. Nonaqueous standards have been published for alcohol – water mixtures [102]. For the preparation of standard buffers in other solvents, see [103].

The glass electrode is useful in nonaqueous solutions, provided it possesses an leached layer which was grown in aqueous solution. It is necessary to regenerate it after some time. Conventional reference electrodes with aqueous potassium chloride can be employed if the solvent is miscible with water. The residual liquid junction potentials are not greater than in aqueous solutions. In some cases, specifically when the sample is immiscible with the reference electrolyte, it is recommended to use an electrolyte bridge with an organic electrolyte solution (Section 3.3).

Here general aspects of pH measurements are described. Numerous examples for laboratory and field measurements be found in [104].

6. Technical pH Measurements

6.1. Extreme Conditions

Diffusion potentials and cross-sensitivies become smaller at *low temperatures*. It is the increase in the resistance of the membrane that causes some problems; this resistance approximately doubles for each 10 K that the cell is cooled. The lower limit of commercial electrodes is − 30 °C. The internal buffer of the glass electrode must contain solvents that act as antifreeze.

The reference electrode requires a reference electrolyte with a low freezing point [105].

The temperature compensation range in most pH meters ends at 0 °C. Sometimes it is possible to make a correction by adjusting k' by means of the slope-correction potentiometer.

The *upper temperature limit* for present-day glass electrodes is 150 °C and lies in the nature of glass on account of the onset of decomposition in aqueous solutions and recrystallization.

Above 150 °C zirconium oxide and palladium hydride electrodes are suitable [106]. With yttrium-stabilized zirconium oxide electrodes measurements are possible in supercritical aqueous systems [107]. For calibrations at temperatures above 100 °C, pH values of standard buffers up to 200 °C are available [62].

Standard glass electrodes withstand a *pressure* of up to 9 MPa. Reinforced glass electrodes can withstand external pressures of up to 15 MPa. Below this pressure, the only complication is the pressure-compensation system for the reference electrode.

If it is only necessary to equilize a few meters of water gauge, then it is sufficient to raise the electrolyte reservoir to an elevated position. For higher pressures, a *pressure chamber assembly*, such as that illustrated in Figure 19 is used. A cylinder, 19 or 25 mm in diameter, equipped with an O-ring for immersion into a matching support, has become standard. A constant inner pressure is limited by the ridity of the reference electrode to 0.3 MPa according DIN 19264 [47]. Higher pressures are possible by pressure control (see Section 6.4).

Pressurized assemblies are equipped with combination electrodes to save space; the electrolyte reserve is accommodated in a cylindrical anlargement of the electrode stem.

In biotechnology sterilization of pH electrodes is necessary. Heat sterilization with saturated steam at 130 °C and up to 0.3 MPa is unavoidable in microbiological applications [108]. The projecting portion of the reference electrode containing the major portion of the electrolyte is not sterilized. It must therefore be assumed that the electrolyte does not contain harmful bacteria, or that these cannot penetrate the diaphragm into the sample solution. Only ceramic diaphragms with mean pore sizes of less than 1 µm are permitted. In addition, the seal between the pressure

chamber and the electrode must not allow leakage of air.

Figure 19. Pressure-chamber electrode assembly (Mettler-Toledo)
a) Combination electrode

6.2. Installation

The high input resistance of a modern pH meter ($R_e > 1\,T\Omega$) is of no avail if the electrical connections of the lead to the glass electrode do not exhibit insulation leakages on this order of magnitude. The insulation resistance of a polyethylene-insulated glass electrode lead is about $100 \times 10^{15}\,\Omega$/m, so that leakage is not expected, even over long runs. However, since the capacitance is 50 – 100 pF/m the cable should be kept as short as possible and installed without avoidable convolutions. All connections must be absolutely watertight.

The glass electrode lead must be shielded completely. In combined electrodes it is permissible to connect the shield of the cable to the reference electrode without earthing. For industrial applications, the shield cable should be earthed following the connection. Since strong induction currents are possible, the lead should be installed in a earthed steel conduit when the runs are long. Since shielded cables are sensitive to movement, they should not be installed on vibrating supports.

Electrical fields can also be set up within the sample solution if stray electrical current flows through it. This source of error is avoided by placing the electrodes within a Faraday cage.

In industrial plants the sample solution is generally earthed. Determinations in low-conductivity solutions and with glass or plastic electrode supports require their own earth. This consists of a massive rod of stainless steel, connected to the casing of the pH meter. To avoid a ground loop, the lead must be installed jointly with the electrode cable. For installation, see [109].

6.3. Electrode Assemblies

Immersion Assemblies. Immersion electrode assemblies, such as that illustrated schematically in Figure 20, are used for determining pH in open vessels. Since the electrodes are immersed below the surface of the liquid the hydrostatic pressure must be compensated by raising the level of the electrolyte vessel. There is no need for a reservoir if the assembly is equipped with a sealed reference electrode containing solidified electrolyte.

The most important application of immersion assemblies is in wastewater treatment facilities where they are mounted in open channels and basins. GÜGEL [110]. A detailed study of the immersion assemblies of several manufactures has revealed that cleaning and maintenance need only be carried out every four weeks and that a measurement uncertainty of $\Delta pH = 0.15$ is to be expected [111].

Built-In Assemblies. Built-in electrode assemblies are used in closed containers. The simplest consist of a mounting plate, like the lower end of an immersion unit, or a simple screw adapter accommodating a combination

electrode. In most cases, pressure compensation is necessary.

If the unit is installed in a vertical wall the electrodes should have an angle of at least 15° with respect to the horizontal, so that the reference electrolyte and the internal buffer will collect in the lower portion of the electrodes.

Figure 20. Schematic diagram of an immersion electrode assembly

Figure 21. Bypass for a flow-through cell
a) Flow-through cell; b) Valves for maintenance; c) Throttle valve; d) Valve for taking samples

Flow-Through Assemblies. Flow-through electrode assemblies are built-in assemblies that are mounted in small vessels and installed in pipelines. The sample stream flows past them. If possible, the sample should flow freely after it has passed the electrode unit so that pressure compensation is unnecessary. Measurements in closed systems require the use of a *bypass* as illustrated in Figure 21. This electrode unit can be removed for maintenance after the valves have been closed.

6.4. Pressure Control

A pneumatic pressure control circuit for an electrode unit is illustrated in Figure 22. A tube for the removal of condensate is also required if the sample solution has a high vapor pressure.

Figure 22. Pressure control of an electrode assembly
a) Pressure vessel; b) Pressurized electrode assembly; c) Control pressure; d) Differential pressure relay; e) Compressed gas supply; f) Top-up pressure supply; P) pressure gauge

A simple arrangement of Figure 23 can be used instead of a differential pressure relay [112]. This device is also applicable in cases where the vapor pressure is high or where aggressive gases are encountered. A small constanty controlled stream of air is blown into the sample vessel through a throttle.

Figure 23. Device for ensuring constant excess pressure in a pressurized electrode assembly [112]

6.5. Retractable Assemblies

When the electrode assembly is installed in a situation where it can not be dismounted without shutting down the plant, it may be advisable to install a retractable electrode assembly. The constructions in general use employ combination electrodes with a pressure chamber.

Figure 24A illustrates an insert with a sliding cylinder. When slid back, as in Figure 24B the closed cylinder form a seal in the bore in front of the electrode assembly. The electrode assembly can now be removed while cylinder seal remains in its seal. In this position the space between electrode and cylinder can be filled with different solutions. It is possible to clean the electrode with chemicals and to recalibrate with buffer solutions. When the electrode has been tested it can be returned to the measuring position.

Instead of closing the cylinder with an O-ring, one can supplement the assembly with a valve [113].

Figure 25. Interchangeable electrode head with divided outer chamber in inspection position [116]
a) Combination electrode; b) Insert; c) Cylindrical seal with O-rings; d, e) Outer chambers; f), g) Outer chamber outlets; h, i) Outer chamber inlets

Retractable electrode assemblies can also be operated pneumatically. The design illustrated in Figure 24 is particularly suitable for this purpose. Operational errors can then be avoided by suitable design of the pneumatic system.

Bioreactors are usually equipped with pressurized-chamber electrode units. In the course of the process it may be necessary to clean and recalibrate the electrode. Steam treatment of assembly in the retracted position does not guarantee sterility. Whatever the construction and sterilization conditions, some parts of the electrode assembly remain inaccessible to the sterilizing action of the steam, and the chemicals and pressurizing air can transport microorganisms into the nutrient. SCHAAD et al. [116] suggested solving this problem with a divided chamber, as illustrated in Figure 25. Both portions can be sterilized with saturated steam. When the electrode is thrust down after sterilization, the front part of the divided chamber is only exposed to already sterilized portions of the electrode assembly. A microbiological filter in the connection to the air line then makes it possible to top up the pressurize.

7. pH Control

General Remarks. It is necessary to keep the pH constant during many industrial processes. Irreparable damage can be caused by brief deviations of the pH, particulary in the case of microbiological processes.

The pH is controlled by comparing the actual value x(pH) of the controlled variable with the desired value w(pH). The desired value can be maintained constant as in a continuous process or it can be altered according to a time table as in a batch process. Control is exerted by a closed circuit known as control loop. This is represented graphically by means of a block circuit diagram, such as that illustrated in Figure 26. Four different functional units can be distinguished in this figure. A control loop is in principle unstable and can oscillate. The greater the influence of the controller on the control parameter, the less stable is the control.

pH Functions. The *stationary gain* Ks is the dependence of the

$$K_s = \frac{\Delta x\,(\mathrm{pH})}{\Delta y\,(q)} \tag{7.1}$$

reagent input x(pH) on the controller output $y(q)$ [117]. In pH control Ks is never a constant value. Its plot as a function of pH is known as a *titration curve*. The slope of pH curves can vary by factors of up to 10^4. Accurate prior knowledge of the titration curve is a prerequisite for pH control.

Figure 27. Titration curve with approximate straight line
Sample 100 mL, acetic acid $c = 1$ mol/L, titrated with c(NaOH) = 1 mol/L

That part of the titration curve which can be expected to encompass the range of the control variable (*control range*) is approximated by a straight line, as illustrated in Figure 27. Although this simplification is sometimes very inaccurate, there is unfortunately no way in which it can be avoided when planning a pH control system. The reciprocal gradient of this straight line is equal to the buffer capacity for flowing systems (cf. Section 1.2)

$$\beta_Q = \frac{\Delta q}{Q \Delta \mathrm{pH}} \tag{7.2}$$

Q is the main stream in L/min and q the addition in mol/min.

For controllability, the response time within the reaction vessel is important. The *step response* gives the progress of pH without any control after the addition of a strong acid or base in one step (Fig. 28). Its form depends on the chemistry and geometry of the reaction vessel. One can distinguish time sections between dead time T_d, *delay time* T_del, and *capacity* or time constant T_c. The rate

$$I_\mathrm{v} = \frac{T_\mathrm{c}}{T_\mathrm{d} + T_\mathrm{del}} \tag{7.3}$$

is decisive for the controllability of the process.

Discontinous Control. *Two-point control* has only two positions for the output: "on" and

Figure 28. Response function. T_d dead time, T_u delay time, T_c time constant

Figure 29. pH transmitter 2500, (KNICK, Berlin).

"off". Such control of pH can be simply and cheaply achieved by installing a magnet valve.

An on – off controller can never maintain the pH at a truly constant value; instead it sets up periodic oscillations. For a comprehensive theory of an on – off control, see [119]. Many pH control requirements can be fulfilled by means of an on – off controller together with a suitable timer the determines the closed and the open times. KUBLI [119] achieved with optimal adaption of t_{on} and t_{off} a ΔpH of ± 0.02 in microbiological reactions.

If it is necessary to control a chemical process by the addition of acid or base, depending on the pH (e.g., when neutralizing wastewaters), it must be possible to activate two control devices at will. Two independent on – off controllers or one three-point controller can be employed for this purpose.

The three-point controller is normally employed in conjunction with a continuously variable control device, e.g., an electric motorized valve or a variable pump. This is a *quasicontinous control* system which has an integral characteristic, since the valve sums all impulses it receives. However such a system is unstable in pH control. The pure integral characteristic of three-point control can be converted by means of feedback. Figure 29 illustrates an industrial pH-meter with incorporated automatic calibration and a three-point controller.

Feedback. It is possible to diminish the amplitude of on – off control by means of a feedback mechanism. This takes the form of an electrical model of the controlled volume made up of capacitors and resistances in abbreviated timescale. The model is wired parallel to and in the opposite sense to the controller. The feedback is applied with a delay time and with a reduced time. After a short period the feedback is slowly reduced and switched off until the controller is actuated once again. This sequence is repeated until the pH deviation disappears.

The control variable responds rapidly at first, and then when it exceeds the level of the proportional adjustment it is only switched on in pulses. This means that the valve setting approaches its new value gradually. The properties of this form of control are very similar to those of a proportional integral differential (PID) controller (see Fig. 30).

Figure 30. Variation of the output of a three-point controller with delayed reducing feedback

The three-term controller with feedback is the most important device used in pH control. It is in no way inferior to a continuous controller. It also delivers the pulsed output appropriate for electric motorized control valves. Since the control

steps are dependent on the impulse width, such controllers are sometimes referred to as *impulse width controllers*.

Feedforward Control. In a simple control circuit, errors of long duration cannot be avoided if, e.g., the input of the supply stream exhibits sudden large changes in flow rate. This is because the pH control system must respond slowly to the pH change for reasons of stability. A *feedforward system* is resorted to in such cases. The rate of flow of the input stream, or other important influence, is monitored and the signal obtained is used to bring about an immediate and proportional change in the rate of addition so that large deviations in the pH are prevented from occurring [120].

Direct feedforward causes the controller output to be multiplied by the relative change in the disturbing variable. In the case of on – off and three-point controllers this can be realized by adjusting the on-time.

Feedforward control can be carried out very elegantly when the pH is controlled by means of a dosing pump, whose stroke and speed of rotation can be altered independently of each other. The speed of rotation can be controlled by the rate of this flow and the stroke can be adjusted according to the pH of the input (Fig. 31).

Figure 31. pH control with feedforward control and dosage pump
a) pH meter; b) Stroke regulator; c) Speed of rotation control; d) Dosage pump; e) Flow measurement; f) Mainstream, g) Additive

Cascade Control. When oscillations reach unacceptable amplitudes, a multistage series of controllers may be useful [121]. The first control loop is responsible for coarse control, where the major proportion of the additive is dosed. The purpose of the second controller is then to smooth out the control errors of the first controller by the addition of small volumes or dilute solutions. Each controller operates independently of the other. Two-step control can also be operated in such a manner that the first step always doses a slight excess and the fine control of the second step corrects this by controlled addition a unneutralized mainstream.

1. Introduction

Metals and their alloys have played an important role in the history of human civilization. This is conveniently illustrated by the fact that two major stages of civilization are known as the Iron Age and the Bronze Age. This helps to place in context the fundamental importance of the discovery, starting in 1982, of a new family of metallic alloys that triggered a deep revision of our understanding of the structure of matter [1–6]. This revision ultimately led to the introduction of the concept of *order without periodicity* (aperiodic order) and, at the same time, spurred intense interdisciplinary activity aimed at a deeper understanding of natural systems in which aperiodic order spontaneously arises.

To understand the conceptual revolution ignited by the discovery of these alloys, it is necessary to recall that the traditional classification scheme of solid matter is based on the notion of *periodic ordering* of atoms in space. It includes two wide categories: crystalline matter, in which the regular location of the constituent atoms determines a long-range order exhibiting translational symmetry; and amorphous matter, in which, although there are correlations in the positions of neighboring atoms, long-range order is completely absent. The implicit dichotomy in this classification scheme made crystalline matter the archetype of *order* in solid-state physics, while amorphous matter represented the paradigm of *disorder*.

This traditional scheme was shaken by the claim that the new alloys, although not conventionally crystalline, nonetheless exhibited discrete, high-quality diffraction patterns. In other words, they could not be regarded as amorphous, since their constituent elements showed a remarkable long-range ordering. The name *quasicrystal* rapidly became popular for this kind of material [7].

From this discovery, the following picture eventually emerged: In quasicrystals, atoms occupy space according to a *quasiperiodic* arrangement instead of the usual periodic fashion observed in crystals. A simple understanding of what a quasiperiodic arrangement might be can be gained by thinking of the Fibonacci sequence. There, the nth number is entirely predictable (the sequence is "ordered") but the rule used to generate it is not analogous to periodicity: each number is the sum of the preceding two, that is, $n_j = n_{j-2} + n_{j-1}$. (This is in contrast to an arithmetic sequence, in which the rule of generation *is* analogous to periodicity.) The geometrical analogue of the Fibonacci sequence constructed by using two types of segments is thought to represent a "one-dimensional quasicrystal", and real quasicrystals indeed often exhibit features which can be described successfully in terms of the Fibonacci sequence.

But in addition to their importance in fundamental research, the interest aroused by these new materials encompassed the field of technological innovations. In fact, the first industrial patent for a straightforward application of quasicrystals was obtained in 1988 [8]. Since then, the number of patents related to quasicrystalline phases has progressively increased and, at present, quasicrystal-containing alloys are pro-

duced at a rate of at least several tonnes per annum.

In the years since their discovery, quasicrystalline phases have been observed in many more alloys, including binary, ternary, and quaternary compounds, mainly based on aluminum and titanium. In addition to the fivefold symmetry axes characteristic of the icosahedral group, eightfold, tenfold, and twelvefold symmetries have been discovered, all of which are incompatible with periodic translational symmetry [3–5]. Figure 1 shows the approximate distribution of the quasicrystalline phases observed to date, according to their symmetries. The overwhelming majority belong to the icosahedral group.

Figure 1. Percentage distribution of the four major symmetry types of quasicrystalline phases obtained to date Icosahedral (i) phases exhibit fivefold symmetry, octagonal (o) phases eightfold symmetry, decagonal (d) phases tenfold symmetry, and dodecagonal (dd) phases twelvefold symmetry

Due to the increasing number and variety of known quasicrystals, the International Crystallographic Union has redefined the term *crystal* to include this new kind of order. In this definition, a crystal is any solid which possesses an essentially discrete diffraction pattern, thus transferring the essential attribute of crystallinity from real space to reciprocal space. Consequently, within the crystalline family we can distinguish between *periodic crystals* and *aperiodic crystals*. This wider definition reflects the present idea that microscopic periodicity is a sufficient but not necessary condition for crystallinity. In this sense, it is interesting to note that the first mention ever made about using the concept of aperiodic crystals in solid-state physics was probably due to SCHRÖDINGER [9], who introduced it in his 1944 discussion on the possible nature of genetic material. Finally, an interesting aspect is the possible relationship between quasicrystalline and conventional crystals, in particular the possible structural transition from one kind to the other, an aspect that has received a great deal of attention.

2. Structural Aspects

A feature of quasicrystalline order is the *self-similarity* of the structure, which constitutes an essential point in most of the structural models proposed for these materials to date [10–14]. This self-similarity and, more specifically, the scale on which features appear self-similar, is referred to as the *inflation symmetry*.

This self-similarity is illustrated in Figure 2, which shows the fivefold arrangement of spots characteristic of the diffraction pattern of an icosahedral quasicrystal and a geometric construction which bears similar properties. (Under many diffraction conditions, a fivefold symmetry like that shown in Figure 2 a appears tenfold because of the introduction of a center of inversion symmetry.) In Figure 2 b, the points of intersection of the lines that join the pentagon vertices define a new pentagon. Its size has a definite relationship to that of the original one, determined by the ratio τ^{-2}, where τ is the ratio between the diagonal and the side of the pentagon. This ratio, corresponding to the irrational number $(\sqrt{5}+1)/2$, has been known since ancient times as the *Golden Mean*, and it is implemented in arts such as painting, sculpture, and architecture. The Golden Mean also describes fundamental properties of the Fibonacci sequence. It is remarkable that the geometric construction shown in Figure 2 b, known as a Pitagoric pentagram, is naturally expressed by the spatial atomic arrangement within a quasicrystal, as can be readily checked by means of a careful comparison with a real diffraction pattern, such as that shown in Figure 2 a. Another remarkable feature of quasicrystalline structures are that they can be "simplified" by lifting them into a higher-dimensional space (higher than the

Figure 2. a) Low-energy electron diffraction pattern of the fivefold surface of an icosahedral phase of an Al – Pd – Mn quasicrystal, in which the existence of pentagonal patterns associated with fivefold axes can be clearly seen [18, 19]. b) Diagram illustrating the self-similarity of the characteristic diffraction pattern of an icosahedral quasicrystal along a fivefold zone axis.

physical real space in which quasiperiodicity is manifested) [15–17].

Clusters containing several tens of atoms are also frequently mentioned in the discussion of quasicrystallographic structure. In particular, Mackay-like clusters and Bergman clusters have been identified in a number of alloys. It has been proposed that these clusters possess a special stability, that they constitute the fundamental building blocks of the solid, and that they are ultimately responsible for all of the unusual physical properties of quasicrystals. This hypothesis remains under active consideration. Figure 3 a shows the structure of one such cluster which may exist in icosahedral Al – Pd – Mn, and Fig 3 shows an arrangement of these clusters along the fivefold axis. Note that the clusters exhibit the same type of inflation symmetry as is illustrated in Figure 2 b.

Atomic quasiperiodic order is not just limited to the bulk of the solid, but is present also on its surface. This is manifest, for instance, in the growth habits of monograins, which in icosahedral systems often display dodecahedral or triacontahedral shapes [20], as predicted by theory [21, 22]. In decagonal systems, the growth habits are typically more anisotropic, yet still can reflect the quasicrystalline nature. Examples are shown in Figure 4 [23–25].

3. Preparation of Quasicrystalline Phases

While many quasicrystalline phases are metastable, a number of thermodynamically stable phases also exist, including Al – Cu – Li, Al – Cu – (Fe, Ru, Os) and Al – Pd – (Mn, Re) [26]. The latter materials preserve a quasiperiodic structure of extraordinary quality until they melt, which occurs at about 1100 – 1200 K. A detailed knowledge of the phase diagrams of such alloys and the corresponding ability to precisely determine the boundaries of the small stability regions of the different quasicrystalline phases have made it possible to grow high-quality single-grain quasicrystals by the conventional Bridgman and Czochralski growth techniques, and by the less-conventional technique of flux growth (slow cooling) [26]. There has been considerable progress in the size and quality of samples available. Optimal single-grain sizes have increased from a few micrometers at their discovery, to about one centimeter a decade later, to about ten centimeters at present.

The discovery of the thermodynamically stable phases also enabled other conventional techniques to be used for preparation of quasicrystals in multiple forms, e.g., gas and centrifugal atomization for preparation of powders; magnetron sputtering for thin films; thermal spray techniques for coatings; and sintering and pressing for solid bodies, to name but a few.

4. Chemical Composition

In Figure 5, the various chemical elements which constitute the different known quasicrystalline phases are indicated via a histogram illustrating their relative frequency of appearance.

Figure 3. a) Structure of a Mackay icosahedron. Similar clusters can be identified in the bulk of icosahedral Al – Pd – Mn and Al – Cu – Fe, although other types of clusters can be identified as well. b) Arrangement of Mackay-type icosahedra showing the hierarchical, self-similar arrangement of overlapping clusters [11, 13, 14].

Figure 4. Single grains of quasicrystals resting on a 1×1 mm grid
A) A single grain of Ho – Mg – Zn. The morphology is that of a pentagonal dodecahedron, consistent with the icosahedral symmetry of the lattice. Photograph courtesy of I. R. Fisher and P. C. Canfield, Ames Laboratory [25]. B) A single grain of decagonal Al – Ni – Co. The long axis of this sample is parallel to the tenfold axis, which is perpendicular to the decagonal (aperiodic) planes. The sample has ten long facetted sides, five of which are visible in the main photograph. The inset shows the face of a similar crystal cut perpendicular to the tenfold axis, thereby revealing all ten facets. Photograph courtesy of I. R. Fisher, N. D. Kelso, and P. C. Canfield, Ames Laboratory.

Aluminum is an almost ubiquitous atomic species in quasicrystals, since it is present in about 85 % of the phases. Other elements which are major constituents of certain quasicrystalline phases include titanium, cadmium, zinc, magnesium, and gallium [26].

The composition of quasicrystalline alloys is quite variable, although it is generally thought to fulfill particular electron-to-atom ratios, similar to the requirement for Hume – Rothery phases [27–30]. The following serve to illustrate some of the known compounds: $Al_{86}Mn_{14}$, $Al_{65}Cu_{20}Fe_{15}$, $Al_{65}Co_{20}Cu_{15}$, $Al_{70}Pd_{21}Mn_{9}$, $Zn_{60}Mg_{30}RE_{10}$ (RE = Y, Dy, Gd, Ho, Tb, Er), and $Ti_{45}Zr_{38}Ni_{17}$. Most known stable phases contain three or more elements, but several

Figure 5. Frequency of appearance of different elements present in the various quasicrystalline alloys obtained to date

two-component systems are notable exceptions: $Cd_{5.7}Yb$ and $Cd_{5.7}Ca$ (both icosahedral) [31] and $Ta_{1.6}Te$ (dodecagonal) [32]. In terms of chemical composition, the largest family consists of alloys with about 60 – 75 atom % Al.

The compositional range which supports a given thermodynamically stable phase is typically very small, spanning only a few atom percent. (Because of this, quasicrystals can be appropriately termed intermetallic compounds.) However, related crystalline phases called *approximants* usually surround the quasicrystalline region in the phase diagrams. The approximants bear strong structural resemblances to the quasicrystals, and their properties are often similar as well. In terms of properties, the quasicrystalline phase typically exhibits a local minimum or maximum value, but the adjacent approximants form a bridge to the ordinary crystalline phases. For some technical applications, the approximants may be even more appealing than the quasicrystals, since they are less sensitive to small compositional changes.

5. Electrical Conductivity

Once the existence of a new kind of ordered matter has been established, it seems natural to wonder to what extent the new structural properties of such materials can determine their transport properties. In the field of quasicrystals, the most widespread opinion is that quasiperiodic long-range order should have a significant impact on most physical properties. And, in fact, from the diverse measurements carried out to date of the electrical resistivity, thermoelectric effect, magnetoresistivity, Hall effect, specific heat, magnetic susceptibility, and optical properties, it appears that the transport properties of quasicrystals are, in general, very different from those expected for a simple combination of the constituent metals [33, 34].

Figure 6. Comparison of the electrical resistivities of some stable quasicrystalline phases and their constituent elements

Figure 7. Comparison of the electrical resistivities of quasicrystals and other broad classes of materials of technological interest

This important result is illustrated in Figure 6, which gives the electrical resistivities ρ measured at room temperature for quasicrystals and their constituent (pure) elements. It can be seen that the isolated elements are good metals possessing low electrical resistivities. In contrast, quasicrystalline alloys comprised of these elements show electrical resistivities which are higher by several orders of magnitude, and much higher than typical values for conventional metallic alloys (both crystalline and amorphous), whose representative values fall in the region between the horizontal dashed lines in Figure 6.

In addition, unlike metals, the electrical conductivity $\sigma = \rho^{-1}$ of quasicrystals *increases* with increasing temperature, instead of decreasing, following a power law of the form $\sigma \propto T^{\alpha}$, where $1/2 \leq \alpha \leq 3/2$. Also in an anomalous manner, the electrical conductivity *decreases* when the quasiperiodic order of the structure is improved, for instance, by means of thermal treatment. And, to complete the list of oddities, electrical conductivity of quasicrystals depends sensitively on the chemical composition of the alloy. This has made it possible to observe a metal–insulator transition for the quaternary icosahedral alloy Al – Pd – Mn – Re, when the Mn content in the alloy is changed by a mere 5 %.

To summarize, thermodynamically stable quasicrystalline phases are clearly beyond the realm of metals in terms of their electrical transport properties, and in fact their inclusion in the category of semiconductor materials has been suggested [35]. In this sense, it is worth mentioning the analogy between the sensitive dependence of conductivity on chemical composition observed, for instance, for the icosahedral $Al_{62.5}Cu_{25}Fe_{12.5}$ alloy, for which an increment of 0.5 % in Al content is enough to double the conductivity value at low temperature, and the characteristic behavior of conductivity in doped semiconductors. In this regard, Figure 7 compares the electrical conductivities of several broad classes of materials.

As with many properties, the effect of quasicrystalline order on transport properties could be revealed best by comparing properties of samples of similar composition but different structure. The discovery of stable phases with decagonal symmetry made it possible to perform these measurements for the same sample, since the decagonal quasicrystals possess periodic order along one direction and quasiperiodic order within the perpendicular plane. In this way, it was confirmed that the electrical resistivity in the decagonal alloys Al – Cu – Co and Al – Ni – Co is high and first increases, then decreases with temperature along the quasiperiodic plane. In contrast, along the periodic axis the electrical resistivity is lower, and increases with increasing temperature, as is typical for crystalline metals [36]. This is illustrated in Figure 8 [24]. Thus, the marked anisotropy in the transport properties must be a consequence of the anisotropy in the sample's structural order.

Why do aperiodic systems exhibit anomalous electrical transport properties? Realistic models must encompass two factors. First, is the marked decrease in the number of charge carriers able to effectively contribute to the electrical conductivity. This decrease, ultimately due

to structural stabilization, is called a *pseudogap* in the density of electronic states. Its existence has been confirmed by means of many experimental techniques [37]. Second is the lack of translational symmetry in these systems (in two or three dimensions), which precludes the usual understanding of extended electronic states in a periodic lattice based on Bloch functions [38].

Figure 8. Anisotropy in the electrical resistivity of decagonal phases [24]

Figure 9. Resistivity at 300 K versus r. The parameter r is defined in the text. The straight line has a slope of -2. Circles represent icosahedral quasicrystals (top to bottom: Al – Pd – Re, Al – Pd – Mn, Al – Cu – Ru, and Al – Cu – Fe), and squares represent approximants in the Al – Cu – Fe system
Courtesy of Jean Marie Dubois, Ecole des Mines, Nancy, France

The real importance of the first factor, the pseudogap, is illustrated in Figure 9, which shows the resistivity ρ at 300 K as a function of a parameter r, which is defined [39] as the ratio of the density of states at the Fermi edge to the corresponding free-electron value, that is, r is a direct measure of the depth of the pseudogap. It turns out that the quasicrystals and their approximants exhibit a relationship $\rho \sim r^{-2}$ at constant temperature, which is obeyed also for disordered systems [40]. While the pseudogap is certainly important, it is not sufficient to explain all the transport phenomena, in particular the anomalous temperature dependence of the conductivity noted above.

6. Thermal Conductivity and Diffusivity

It is well known that most metals are good conductors of heat, and that thermal conductivity is proportional to the product of their electrical conductivity and temperature. None of this holds true for quasicrystals, which are very bad conductors of heat, basically because the density of free electrons is low. Consequently, heat must propagate by means of atomic vibrations (phonons). Phonons, which are periodic waves, do not travel easily in an aperiodic lattice once their wavelength becomes comparable to the size of the constituent atomic clusters, that is, above about 70 K. Furthermore, the vectorial combination of two phonons travels in the opposite direction [an Umklapp process; German: *umklappen* = fold back)) to that of the incident phonons in quasicrystals, in strong contrast to the case of regular crystals, in which such a combination is favorable to heat transport. Finally, quasicrystals contain a large number of atomic sites with two nearly equivalent equilibrium positions. Such so-called phason sites may be excited by the traveling wave and hence absorb part of its energy. This also inhibits the conduction of heat.

Some representative values for thermal conductivities (in $\mathrm{W\,m^{-1}\,K^{-1}}$) of quasicrystals and other materials of industrial interest are listed in the following:

Ag	420
Cu	380
Al	209
Fe	59
GaAs	40
SiC	35 – 155
TiC	33
TiN	24
Al_2O_3	27 – 43
Decagonal quasicrystals	1.5 – 2.5
Icosahedral quasicrystals	2
Yttria-doped zirconia	2
Pyrex	1.3

The thermal conductivities of quasicrystals, both decagonal and icosahedral, are clearly lower than those of thermal insulators that are extensively used in aeronautical industry, such as titanium carbides or nitrides, doped zirconia, or alumina. In addition, the thermal diffusivity of these new materials is extraordinarily low, even lower than that of zirconium oxide. And, remarkably, the value of this diffusivity increases only by a factor of two with increasing temperature until the material melts.

7. Mechanical and Surface Properties

Table 1 compares mechanical and surface properties of quasicrystals with those of more common materials. The focus on the quasicrystalline phases in the Al – Pd – Mn and Al – Cu – Fe systems is because these data are more abundant than for other quasicrystalline alloys. The quasicrystals are noteworthy for their hardness, low surface energy, and low friction. An unattractive property is brittleness, as gauged by their low fracture toughness. Other attractive properties, for which data are not shown, include oxidation resistance, hydrogen storage capacity, and transition from brittle to ductile behavior at about three-fourths of the melting point.

Quasicrystals are very brittle. The toughness of single grains is less than 0.5 MPa $m^{1/2}$. In contrast, metallic crystals like aluminum are characterized by toughnesses about two orders of magnitude higher. As a result quasicrystals have little resistance to crack propagation below 450 °C. Hence, they are not very useful as bulk materials but may be more fruitfully employed as surface coatings or as composites. In such a case, the mechanical integrity is supplied by the substrate or the matrix, while the quasicrystal offers supplemental functions. For instance, in a coating, this may be hardness, protection against corrosion, optical absorbance, etc.

However, the brittleness of quasicrystals is overcome at high temperatures. Above about 450 °C, quasicrystals become plastic and deform more and more with applied stress. Deformation is facilitated by dislocations, as in conventional crystals. However, in contrast to conventional crystals, there is no work hardening. This proves the absence of pinning centers and indicates a viscous flow regime that might be due to some internal friction between supposedly undeformable atomic entities. Current research seeks actively to understand the plasticity of quasicrystals. In the same temperature range, it is also observed that thermal vacancies multiply and play the key role in atomic transport over large distances. Accordingly, diffusion coefficients of quasicrystals in the temperature range above 450 °C are similar to those measured in aluminum-based intermetallics. Similarly, the oxidation resistance of quasicrystals does not significantly depart from that of aluminum alloys or compounds. When in contact with pure O_2 or air, the quasicrystal surface is soon covered by a thin layer of pure alumina. Again, two temperature regimes may be distinguished, below and above 450 °C, with slow and quick formation of the oxide film, respectively.

Easy crack-propagation brittleness is indicative of a low cleavage energy (the energy required to split a crystal into two parts with no plastic deformation; for instance, at very low temperature). This energy is equal to twice the surface energy of the material, since two fresh surfaces are created by propagating the crack. In good metals like aluminum, the energy of the clean-surface is typically 1 J/m^2. No investigation of the clean surface energy has yet been performed on quasicrystals. Nevertheless, indirect evidence that the surface energy of quasicrystals is indeed small may be deduced from a comparison of contact angles measured by depositing small liquid droplets on the surface of a quasicrystalline sample as well as on reference samples such as teflon, metals, or a bulk oxide such as alumina. By using the approach developed two centuries ago by Young, and making certain assumptions, the contact angle can be related fairly simply to the reversible adhesion

Table 1. Comparison of the properties of quasicrystals with those of common metals and nonmetals

Material	Density, g/cm^3	Hardness, HV	Fracture toughness, MPa m$^{1/2}$	Young's modulus, GPa	Coefficient of friction ∗	Adhesion energy with water, mJ/m^2
Quasicrystals						
Icosahedral Al – Pd – Fe (single grain)		700 – 900	0.3	200	0.055	72
Icosahedral Al – Cu – Fe (polygrain)	4.6	800 – 1000	1.6	68 – 85	0.046	55
Common metals						
Copper			30	130		105
Aluminum	2.9	25	40	70	0.112	98
High-carbon steel		881			0.071	98
Low-carbon steel	7.8	120		215		
Nonmetals						
Yttria-doped zirconia	5.6					
Alumina		1950	4.7	300	0.067	120
Diamond		>5000			0.04 – 0.05	

∗ Unlubricated, with respect to a diamond pin in air.

energy W_L of a given liquid onto the surface, larger angles and poorer wetting corresponding to smaller values of W_L.

Poor wetting is an appropriate description of the interaction between carefully polished Al-rich quasicrystals and water. Correspondingly, their reversible adhesion energy with water is only 25 % larger than that of teflon (55 and 44 mJ/m^2, respectively) and one-third of that of window glass. The fundamental origin of this behavior is not yet understood, but a natural question is whether it is controlled by the properties of the surface of the quasicrystal, or those of the bulk. Quasicrystals always carry a thin surface oxide layer, consisting mainly of aluminum oxide. However, bulk alumina is comparable to window glass in that it is wet completely by water, indicating a high value of W_L. Thus, wetting of the quasicrystals is probably not controlled, at least to zeroth order, by the surface layer, but rather in some way by the underlying atomic and electronic structure of the bulk. (Note that this discussion is only demonstrably valid for water; common organic solvents wet quasicrystals well, and this indicates that the wetting may depend on the polarity of the liquid.)

Surface friction is a further important issue for quasicrystals. As shown in Table 1, numerous experiments using a spherical diamond pin have demonstrated that friction is lower on a quasicrystal ($\mu = 0.04 - 0.05$) than on steel ($\mu = 0.07$) of comparable hardness. With more conventional riders such as mild steel or WC – Co, the comparison is less favorable due to the transfer of material from the indenter to the surface. During such friction measurements, a major drawback arises from the brittleness of the contacting bodies and hence formation of wear particles. However, scratch tracks indicate that quasicrystals subjected to repetitive and severe shear develop some ductility during this process, and consequently acquire an ability to self-repair. This brittle-to-ductile behavior might be associated with the nucleation of crystalline nanometer-sized grains within the quasicrystalline matrix [41].

8. Potential Applications

Applications of quasicrystals, both real and anticipated, can be placed into two categories: composites and coatings. (The term composite is used very broadly to include multiple-phase materials produced both by artificial mixing and by natural precipitation.) In both forms, the brittleness which characterizes the bulk material is mitigated. Among the composites, a precipitation-strengthened steel is marketed by Sandvik Steel in Sweden. The precipitates are quasicrystalline. The steel is strong, relatively ductile, corrosion-resistant, and resistant to overaging. The quasicrystalline precipitates are numerous, and resist coarsening during aging. Both of these effects must reflect a low interfacial energy. The steel is attractive for tools in the health industry (surgery, dentistry, acupuncture) and makes up key components of an electric shaver currently marketed by Philips.

Another type of bulk composite is an Al-based alloy which can be formed by rapid solidification and powder processing. The quasicrystals form by precipitation, yielding nanoscale particles surrounded by an Al matrix. Certain compositions can exhibit especially high strength or high ductility [42]. One such alloy, Al – Fe – Cr – Ti, exhibits sufficiently high strength at elevated temperature that it meets an air-force goal level for Al-based alloys. The optimal mechanical properties of these composites, taken over all icosahedra-forming compositions studied to date, are mapped by the outer envelope in Figure 10. The properties are compared with those of a more common Al alloy, for which data are shown by the inner envelope. In all cases (except, of course, thermal expansion), the quasicrystalline-rich composites excel. Gigas, in Japan, markets these materials as extruded bars and preformed parts.

Figure 10. Map of the physical properties of Al quasicrystal composites in comparison with a conventional Al alloy
Courtesy of Akihisa Inoue, Tohoku University, Japan

A type of composite which is promising, but not yet marketed, involves polymers with quasicrystalline fillers. Tests with certain high-performance thermoplastic resins have shown that quasicrystalline AlCuFe particles enhance the wear resistance of the polymers significantly. This effect is not understood, but may be related to a combination of the hardness, low friction, and low thermal conductivity intrinsic to the quasicrystal. At the same time, key thermochemical characteristics of the polymer, that is, its glass and melting transitions, are not degraded, and this indicates that the quasicrystal does not catalyze cross-linking or other disadvantageous reactions in the resin.

Thermal barriers can be manufactured as thick coatings by thermal spraying techniques or magnetron sputtering. This application relies upon bulk properties of quasicrystals, namely, low thermal conductivity and plasticity at high temperature. As such, the quasicrystal is a poor heat conductor which is additionally able to resist the shear stress, if any, generated at the interface with the substrate due to the difference in thermal expansion coefficients. In contrast to zirconia, such a difference is small, since expansion coefficients for quasicrystals, in the range of $(13-16)\times 10^{-6}\,\mathrm{K}^{-1}$, are close to those of metallic alloys. In comparison to metals, quasicrystals also resist oxidation and corrosion by sulfur at high temperature. The main drawback to using quasicrystals comes from their rather low melting temperature and significant atomic mobility. Intercalation of a thin diffusion barrier, typically made of an oxide such as Y_2O_3, allows the latter difficulty to be overcome easily. A specific composition with nearly congruent melting at 1170 °C was developed to enhance the temperature range in which quasicrystalline thermal barriers may be useful. Although not competitive with doped zirconia above 1050 – 1100 °C, such barriers were successfully tested at 950 °C in a real-time ground test of an aircraft engine. Application to other combustion engines, to power generators or, in general, to heat insulation of fast-moving mechanical parts is also of interest.

The potential application for which quasicrystals have gained most attention is as coatings which combine wear resistance with low friction and/or low adhesion. A commercial product which exploited these properties was the quasicrystal-coated frying pan marketed by Sitram. The quasicrystal coating is not directly competitive with Teflon in terms of its nonstick properties, since the work of adhesion of the quasicrystal with water, for instance, is not as small as that of Teflon with water, but adhesion for many foods is reduced relative to a conventional metal pan, and the coating is much harder than Teflon. The hardness means that normal cutlery can be used with the quasicrystal coating, an attractive feature relative to Teflon. Furthermore, the low thermal conductivity also presents an ad-

vantage in the cookware, since it leads to even surface heating. However, it appears that technological problems with the manufacturing process remain to be solved, which points toward the importance of coupling good basic research with technology development in the area of quasicrystals.

The frying pan is a good example of the general need to balance hardness and surface properties in coatings. The place of the quasicrystal in the general scheme is illustrated in Figure 11. It can be seen that the quasicrystal is quite hard, yet offers unique surface properties.

Figure 11. Reversible work of adhesion of water W_{water}, derived from contact angle measurements, as a function of Vickers hardness for various common materials. The size of the symbols shows the range of properties within each family of materials. The straight line shows the relationship expected between hardness and reversible work of adhesion: $H^{1/3}/W =$ constant. Such a selection chart emphasizes the advantage of quasicrystals in terms of striking a balance between adhesion and hardness.

Although one product has been marketed, optimization of coating properties for wear-resistant, low-friction, and/or low-adhesion applications still requires much technological development. One problem is that coatings commonly contain significant levels of phase impurities, which can make them more susceptible to wear by brittle fracture than the pure quasicrystal. The phase impurities arise from the complex solidification pathway of quasicrystals and from other technical problems of fabrication, mostly related to the low thermal conductivity. The wear can also lead to a large increase in the friction coefficient. One possible solution to this problem is the addition of a very small amount of the more ductile phase Fe – Al to a plasma-sprayed coating of Al – Cu – Fe to improve the coating's wear properties. Obviously, the properties of the quasicrystalline coatings are very sensitive to the phase purity, and more specifically to the exact nature of the secondary phase(s).

Some potential applications not mentioned in this article are hydrogen storage, catalysis, thermoelectrics, and optical absorbers [43]. While promising, these applications seem farther from realization than those mentioned above.

Many aspects of the technologies pertaining to quasicrystals have been patented [8, 44–65]. For more scientific details, see [34, 66–69].

In summary, quasicrystals constitute a fascinating scientific frontier, and a barely-explored source of new technologies. A central question, which happens to unite the two frontiers, is this: Why does their remarkable atomic structure lead to unusual physical properties? We believe that the answer to this question will continue to evolve, hand-in-hand with the evolution of new applications.

1. Introduction

DNA is a biological polymer made from very simple building blocks but exhibiting large-scale complexity. It is the complexity which lends this remarkable molecule its power to control cells, tissues, and ultimately organisms. It is also this complexity which is looked at when DNA is analyzed. The length of the molecule gives a sense of scale. For example, each human chromosome contains DNA varying between 1.4 and 7.3 cm in length, depending on the chromosome.

1.1. DNA Structure

DNA is composed of a chain of nucleotides, each of which is made up of a deoxyribose sugar, a phosphate group, and a base. Variety in DNA stems from the bases; these can be either adenine or guanine (purines), or cytosine or thymidine (pyrimidines). The phosphates and sugars provide the external backbone from which the bases project. The backbone is constructed of sugars attached to each other by formation of a phosphate ester between the 3′-hydroxyl group of one sugar and the 5′-phosphate group on the next sugar; the DNA molecule is therefore polarized 5′ to 3′.

The double-helix structure is formed by two strands of DNA pairing in opposite polarities. The phosphate – sugar backbone is on the outside, and the bases project into the middle. While the components of the individual strands are held together by covalent bonds, the two strands are held together by hydrogen bonds between the bases.

The four bases associated with DNA, which are generally referred to by their initial letters, are adenine (A), cytosine (C), thymidine (T), and guanine (G). These bases key together from opposite strands in a very particular way. A only pairs with T, and G only pairs with C. The association is controlled by formation of hydrogen bonds (Figure 1).

It is the delicacy of the hydrogen bonds compared with covalent bonds which lends both functional performance and elegance to DNA. The conformation of the double stranded helix can be visualized as a right-handed spiral staircase with 10 steps (bases) per complete revolution and a diameter of approximately 2 nm. As a consequence of this structure, it is not possible to separate the two strands without unwinding the helix.

Figure 1. Normal base pairing found in DNA between adenine and thymine and between cytosine and guanine

It is a useful convention when dealing with DNA to ignore the sugars and phosphates and merely refer to the bases of a single strand. This is because the exact bonding of one strand with another allows the complementary sequence of any given single strand to be precisely determined. Consequently, when a DNA sequence is written out, it is conventional only to list the base sequence of a single strand, the other being explicitly determined. Note that genetic complexity is not directly related to DNA content of a cell. This can be broadly seen in Table 1.

Table 1. DNA content in picograms of a range of species

Species	Common name	Nuclear DNA content, pg
Saccharomyces cerevisiae	yeast	0.026
Drosophila	fruit fly	0.1
Mus musculus	mouse	2.5
Homo sapiens	man	3.7
Avena sativa	bread wheat	18.1
Protopterus	lungfish	50
Fritillaria davisii	lily	98.4

The huge differences in DNA content are generally associated with variations in the amount of repeated sequences present. The complexity of the genome, that is, the proportion of repeats compared with a unique sequence in any given organism, is determined by using Cot curves, Cot being the concentration (Co) of DNA in moles of nucleotide per liter multiplied by the renaturation time (t) in seconds. Calculation of Cot values is complex, but they are always presented in a uniform way. The values are plotted on a log scale to give a curved plot whose slope gives an indication of the level of repetition in the DNA sample. Cot curves are based on the fact that DNA can be denatured by heat and reanneals when the temperature drops. This behavior also forms an important part of many other methods of DNA analysis.

When DNA is cut into short sections of about 400 – 600 bp (base pairs) and these fragments are then denatured, the highly repetitious sequences reanneal first, simply because the repeat sequences are more likely to come into contact with complementary sequences. The more complex the genome is the longer it takes low- or single-copy sequences to find the right partner.

1.2. Structure of DNA in Vivo

DNA does not sit in cells in an uncontrolled manner. It is regulated in both its position and expression. These are carried out by proteins, genetically silent, but of huge importance. The proteins involved in structural control of DNA are some of the most highly conserved found in the living world. While it is not the remit of this article to detail the manner in which DNA is controlled within the cell, it is worth noting the first-order structure of chromatin, this being the term used to describe the DNA – protein complex.

By using osmotic shock it is possible to unwind chromatin to show the fundamental unit as a beaded string of about 10 nm in diameter. The beads are histone proteins, around which the DNA double helix is wrapped. Histone proteins are almost exclusively associated with nuclear DNA. The five different histones associated with DNA, designated H1, H2A, H2B, H3, and H4, have been highly conserved throughout evolution, and this indicates their fundamental importance to the integrity and control of DNA. Changes to histone proteins by methylation, phosphorylation, etc., have effects on the charge of the protein, which can alter the interaction between histone and DNA. For example,

acetylation of histone H4 results in unfolding of the nucleosome core and is associated with transcriptionally active regions of DNA.

Beyond this level of organization the DNA – histone complex is repeatedly coiled such that the whole strand becomes shorter and shorter and more tightly controlled. The ultimate winding step results in a chromosome, which during certain stages of the cell cycle is sufficiently well condensed to be visible with a light microscope, and specific staining techniques can be used to identify individual chromosomes. Visualizing chromosomes is relatively easy in eukaryotes, that is, higher organisms with a clearly defined nucleus. However, in prokaryotes such as bacteria, the nucleic acid is not generally associated with histone proteins, and single chromosomes are often circular. This reflects the simplicity of the genome. For example, humans, who do not have the largest genome in the animal kingdom, contain approximately 3000 million base pairs, while the gut bacterium *Escherichia coli* contains 4 720 000 base pairs and a virus which infects *E. coli* with the designation ΦX174 contains 5386 bases of single-stranded DNA.

2. Primary Molecular Tools for DNA Analysis

With DNA being such a large molecule it is important to be able to manipulate it effectively. This can take any form of manipulation from the entire chromosome, or to just very small pieces of DNA of particular interest. To make these manipulations various enzymes are used which are a part of a cell's own ability to alter the activity of DNA and in some cases protect the cell from invasion by pathogens.

The most important types of enzyme used in molecular biology are:

- Exonucleases
- Endonucleases
- Polymerases
- Ligases
- Methylases

Exonucleases and endonucleases are collectively referred to as DNases, or more fully deoxyribonucleases. Enzymes which can degrade both DNA and RNA are called simply nucleases. If a DNase cuts only one strand of a double-stranded molecule it is called a nicking enzyme, and the resultant single-strand break is a nick. One such enzyme is Dnase I. These enzymes seem to be important in releasing tension in the double helix as it is unwound during replication.

Exonucleases degrade DNA from the ends and cannot themselves generally introduce breaks within a strand. For example, mung bean nuclease progressively remove bases from both the 5′ and 3′ ends of DNA where there is an overhang, resulting in two blunt ends, that is, strands of equal length of complementary sequences. In contrast, exonuclease III preferentially degrades recessed 3′ ends, that is, where the complementary strand extends beyond the 3′ end. If the 3′ end overhangs by more than four bases, the enzyme cannot attack it. This property can be exploited by first nicking the DNA at specific sites with an enzyme and then using exonuclease III to create a single-strand gap propagating in a specific direction.

Endonucleases cut DNA internally, rather than at the ends, and are more correctly called restriction endonucleases. The activity of endonucleases can vary widely from enzyme to enzyme. Several hundred are now known, with very different operating conditions and sites at which they restrict, or cut, the DNA. Endonucleases recognize short sequences along the DNA, which may occur once every few hundred or few thousand bases along the molecule. The frequency with which cutting sites can be found depends largely upon either how specific the sequence must be or how long the sequence must be before it is recognized by the enzyme.

Most endonucleases recognize sites between four and six bases long and cut the two strands either symmetrically or staggered. A range of such restriction endonucleases and their restriction sites are shown in Table 2.

Table 2. A range of enzymes and their cutting sites

Enzyme name	Restriction site
Nae I	5′ . . .GCC↓GGC. . .3′
	3′ . . .CGG↑CCG. . .5′
Nco I	5′ . . .C↓CATGG. . .3′
	3′ . . .GGTAC↑C. . .5′
Hae III	5′ . . .GG↓CC. . .3′
	3′ . . .CC↑GG. . .5′
Mbo I	5′ . . . ↓GATC. . .3′
	3′ . . . . . .CTAG↑ . . .5′
Msp I	5′ . . .C↓CGG. . .3′
	3′ . . .GGC↑C. . .5′

The names are generally derived from the initials of the organism in which the particular enzyme was found; for example, all restriction enzymes beginning *Eco* are derived from *Escherichia coli.*

Using any given endonuclease on a specific piece of DNA always gives the same number and size of fragments. With large genomes there can be variation between individuals, but with very small genomes, as found in viruses where there is no sexual reproduction, the variation in restriction sites between individuals is effectively zero. So using a restriction endonuclease on such material results in fragments of exactly known size. These could then be compared with unknown fragments to give information about the DNA under analysis. An example of this is the digestion of a small plasmid of 4361 base pairs, designated pBR322, which is usually found in *E. coli*. Digestion of this with the endonuclease *Msp* I always results in 26 fragments ranging in size from 622 base pairs (4.04×10^5 Da) to only nine base pairs (0.06×10^5 Da).

Polymerases take individual nucleotides and attach them to a progressively lengthening chain of DNA. In living cells they perform the essential function of DNA replication. This is also exploited in vitro to produce multiple copies of specific regions of DNA. In cells, polymerase is controlled by a battery of associated enzymes. All known polymerases replicate in the $5' \Rightarrow 3'$ direction. In the laboratory, a different approach must be taken to make full use of the technique.

There are many different types of DNA polymerase, most of which are, like most enzymes, unstable at high temperatures. These enzymes are of a specific value in some circumstances. For example, T7 DNA polymerase comes from bacteriophage T7, which attacks *E. coli* by taking over cellular control and replicating its own DNA. This enzyme can be very useful for replicating long stretches of DNA quickly. Sometimes a short section of DNA must be replicated, but more than once, and for this thermostable enzymes are needed. The first of these was extracted from a deep sea species *Thermus aquaticus* and called *Taq*. Later other forms of heat-stable DNA polymerases were found in other species living around deep-sea thermal vents. These enzymes tend to make fewer errors in replication. They include a DNA polymerase from *Thermococcus litoralis*, which lives in a marine environment at 98 °C, and one extracted from a species of *Pyrococcus*, recovered from a deep-sea vent at 2010 m and capable of growth at 104 °C.

The value of these thermostable enzymes is that they can easily be used in polymerase chain reactions (PCRs), a technique in which short sections of DNA are replicated exponentially (see also → Polymerase Chain Reaction). By knowing two short sequences of DNA on either side of the target DNA, which itself can be of a completely unknown sequence, it is possible to produce single-stranded primers, complementary to the two sequences. At this stage the target DNA is double stranded, held together by hydrogen bonds. Exposure to heat denatures the DNA and results in single-stranded DNA. On cooling the sample at this stage, to a temperature at which the DNA will reanneal, some complementary strands will rejoin, but many of the primers will attach to the single-stranded DNA. Increasing the temperature at this point to below the denaturing temperature allows the DNA polymerase to extend the strand by adding on bases that are also present in the solution. This cycle is repeated until enough target DNA is present for further analysis [1].

PCR is one of the most powerful methods of producing material for analysis from very small samples. If PCR were 100 % efficient, then after 20 cycles there would be 2^{20} times the number of starting molecules, each with a primer at one end. It is these primers which can be tagged, if required, for later detection. Every primer detected which exceeds the original primer in mass implies the presence of an amplified product. After approximately 25 – 30 cycles the enzyme

limits the reaction and so, in conjunction with other factors, this results in a realistic 10^6-fold increase in target DNA. One such limiting factor is that as PCR proceeds and more complementary DNA is produced, so there is an increasing tendency for complementary strands to anneal, to the exclusion of the primers. Figure 2 illustrates the temperature cycles and the increase in amplified product.

Figure 2. The polymerase chain reaction temperature cycle. The exact temperatures depend upon the type of primers; AT-rich primers are more easily denatured than GC-rich primers.

Ligases reattach strands of DNA together. Ligases come in many forms, some only able to work on single-stranded DNA or RNA, while others act on duplex strands. Another major difference between ligases is the ability to reseal a single-strand nick created by a nicking enzyme. Although some ligases only reattach blunt ends, single-base overhangs, or cohesive ends, that is, two single-strand overhangs with exactly complementary sequences, all ligases operate in the same way. The enzyme catalyzes the formation of a phosphodiester bond between juxtaposed 5′-phosphate and 3′-hydroxyl termini of two adjacent oligonucleotides.

Methylases chemically modify DNA residues. In higher eukaryotes this usually takes the form of attachment of a methyl group to cytosine to form 5-methylcytosine. Usually the methylated residues are in C – G pairs. The level of methylation of eukaryote DNA shows a strong correlation with transcriptional inactivity. Lower eukaryotes and prokaryotes are also able to methylate adenine residues. There are no known methylases that act on guanine.

Methylases have recognition sites in which they work, so it is generally possible to tailor the methylation to a specific area of DNA. The value of this stems from methylated residues being resistant to attack from restriction endonucleases. This allows the bacteria carrying endonucleases for protection against invading viruses to protect their own DNA by methylation. It is this aspect of methylases which is important in DNA analysis.

3. Methods of DNA Detection

Once a DNA sequence of interest has been produced by PCR or extracted from a cell, there are several further stages which can be used to determine more about the DNA. Broadly speaking, two aspects can be investigated: size and sequence. Often, for practical purposes, sizing alone is sufficient to detect, say, a mutation of medical importance [2]. In some cases, sizing of some specific fragments may be enough to allow determination of a sequence.

Sequencing is generally undertaken only when absolutely necessary, because of cost and time constraints. The best known sequencing effort is the Human Genome Mapping Project (HGMP). This is intended to sequence the entire human genome, but it should not be imagined that the story ends there. The reading frame of much of the DNA is still unknown, and it is also unknown what most of the sequences are for, if anything. Consequently, knowing a sequence is only the start.

There are several different ways in which DNA can be detected and sized, the majority of which involve separation of different sized DNA fragments under the influence of an electric current (electrophoresis). The medium for gel electrophoresis varies from simple agarose to polyacrylamide.

The earliest method for detecting DNA fragments after electrophoresis was the Southern blot. It involves transfer of the various discrete fragments to a solid support, where they are immobilized. This transfer is accomplished by capillary action in SSC (sodium chloride – sodium citrate) buffer. The capillary action transfers the DNA to a nylon or other artificial membrane, after which it is fixed by heating to approximately 80 °C. The transfer takes place on an horizontal

bed, so the relative positions of the DNA does not alter. Treating the DNA on the blot with probes that have complimentary sequences to those which are under investigation yields a series of bands that can be taken as representing the positions of those known, probe, sequences of DNA. These probes are not irreversibly bound to the membrane, unlike the DNA under investigation, so they can be removed, and a different probe, or probes, hybridized.

Broadly, there are two different types of probe: multilocus probes (MLP) and single-locus probes (SLP). Multilocus probes hybridize at several different sites on the genome, while single-locus probes only hybridize to a single site. Hence, an MLP will give a multi-banded result, but an SLP will give a maximum of only two bands per probe per individual.

The reason for the maximum of two bands is that all higher organisms carry two copies of every gene, one from each parent. When using SLPs these may be both the same (homozygous) and result in only a single band. However, when the two alleles are different (heterozygous) an SLP will produce two bands. Whichever of these systems, SLP or MLP, is used, indeed, whenever a gel separation system is used, an internal size standard is required. This either an allelic ladder or DNA digested by a specific enzyme yielding fragments of known sizes. The comparison of fragment sizes is generally referred to as the Local Southern method. It takes into account the tendency of DNA fragments that are similar in mass to migrate in a generally linear fashion relative to each other. It therefore requires at least three DNA mass markers which are close in size to the fragment of interest so that an accurate comparison can be made. It is important that the DNA mass markers are closely associated with the fragments under investigation because as they depart in mass, the calculation of mass by comparison becomes increasingly inaccurate.

This technique of comparison of size of DNA fragments against a standard is still the best and most accurate method of determining the size of a piece of DNA when it is either fixed on a membrane or travelling through a gel. This extends to other techniques which do not require the use of a membrane blot to transfer DNA to a solid substrate.

While the original method of DNA analysis required the transfer to a membrane of DNA that had been separated by gel electrophoresis before further analysis could be undertaken, more recent developments have rendered this unnecessary except in specific areas of research. However, automated systems still require a method of sizing which is both reliable and repeatable, and so DNA fragments of known mass are still the method of choice.

Techniques for detection of DNA on gels has also changed. In the original method, ^{32}P, which has a half-life of approximately 14 d, was substituted for a nonradioactive P atom in the DNA probe. When hybridized to the probe and exposed to X-ray film, the film would darken at the radioactive sites. Besides the short half-life, two other major considerations spawned research into nonisotopic detection of nucleic acids: potential long-term health hazards and disposal of residual radioactive material from the assay. Most chemical detection techniques were based around immunoassay tests and then developed further.

Nonisotopic labeling to detect nucleic acid – probe hybrids can direct or indirect [3]. Direct methods involve attaching a detectable label directly to the target, usually the probe, by a covalent bond. This technique is now employed in machine-based systems, but on gels it is still common to use an indirect method. This involves a hapten, a low molecular mass molecule (usually < 1000), attached to the probe, which can then be detected by using a specific binding protein, which may be antibody based. Although the binding strategy should avoid involving the hydrogen bonds, which are essential for binding of probes to the target DNA, this is not always practicable and may partially compromise the efficacy of the system.

The sensitivity of hybridization assays is a function of the detection limit of the label, some of which are not only as sensitive as radiolabeled assays, but are much faster in exposure times to X-ray film. There are four broad categories of detection for nonisotopic labels: bioluminescence, colorimetry, electrochemiluminescence, and fluorescence.

3.1. Bioluminescence

This is essentially the same as chemiluminescence found in nature, for example in fireflies

and certain types of fungi and bacteria. They involve the use of a luciferin substrate and an enzyme, luciferase. Because of the versatility and sensitivity of these systems, they can be used with either film or charge coupled device (CCD) cameras.

3.2. Colorimetry

Systems using colorimetry tend to be less sensitive than luminescent systems, but they do have some advantages. By producing a precipitate associated with the DNA – probe hybrid, they are ideal to produce a permanent record of the distribution on a membrane.

3.3. Electrochemiluminescence

Electrochemiluminescence is a specialized technique in which an electrochemical reaction produces an excited state, after which decay to a ground state produces light. The special facilities for electrochemical generation and detection renders this type of system expensive.

3.4. Fluorescence

Fluorescence detection is the system of choice now generally employed in automated equipment. Straightforward fluorescence detection of DNA on gels by film or CCD device, is difficult because of intrinsic problems of noise. However, specific fluorochromes have enabled systems to be developed which utilize different methods of detection, rather than simply overlaying a gel with a photoreactive paper.

Fluorescence detection of specific dyes at specific wavelengths has revolutionized not only the detection of target alleles, but also personal identification, paternity details, and DNA sequencing. This technology has been implemented in many different systems using a range of equipment. A common method for detection of specific fragments is to attach a dye to either an oligonucleotide primer, for use in a PCR reaction, or a probe. By using different fluorochromes for different oligonucleotide primers it is possible to run several PCR reactions simultaneously in the same reaction vessel. Detection involves inducing fluorescence with a laser, the data being captured and processed automatically as the DNA fragments pass in front of the laser. Thus, an image can be created from the data which broadly corresponds to the older autoradiograph image created from Southern blots and probes. However, this is not actually the most convenient method of data display. The graphic display in Figure 3 is the more usual method of showing results of analysis.

By using four different dyes (red, blue, green, and yellow), large numbers of reactions can be carried out in a single tube. It is also possible to include size standards, which makes accurate sizing of fragments much more precise. Figure 4 shows the emission spectra of the various dyes in commercial use. Even if two different fragments have the same molecular mass, povided they fluoresce at different wavelengths they can be separated by using filters. Since many of these dyes are proprietary products, their exact chemical constitution has not been released.

So far these methods have broadly been applicable to slab gels, but more recently capillary electrophoresis for DNA has been introduced. The main advantage of this system is speed and reproducibility. Arrays of capillaries are used instead of a single gel, but in general terms the technology is very similar and the output identical.

As new technologies are introduced there is a move away from gel-based systems towards more exotic methods of DNA analysis. One such is the DNA chip. This is a technology still in its infancy, but potentially of great power and speed. DNA chips utilize the negative charge on DNA to move it about and concentrate it in target areas. These target areas have probes chemically bound to the chip. After several cycles of DNA binding to the chip, each with a different probe, the same process is repeated, but this time with the DNA to be analyzed. By concentrating the DNA around the probes, hybridization rapidly takes place. The bound DNA is detected with a laser and arrays to detect the resulting fluoresence. As can be readily appreciated, although potentially very useful, the difficulty is in making the chips flexible enough to be applicable to any but the most specialist of areas of research and diagnostics, where mass screening would make the system commercially viable.

Figure 3. Graphic display of output from an automated DNA analyzer. By using loci of widely differing sizes in the same lane, they can use the same laser-activated dye without risk of confusion. This is a composite image of data generated on the basis of when each fragment passes the laser window. It is therefore not a static image but based on a dynamic timescale. The higher molecular mass fragments are towards the right-hand side of the display. Note a size maker is still needed, at the bottom; itfluoresces red. Since all the alleles are separable, they can be run in a single column, the image being generated by the associated computer.

One of the most useful techniques to help in understanding DNA and genes is DNA sequencing, which determines the precise arrangement of bases making up the DNA. This has received considerable public exposure with the advent of the Human Genome Mapping Project (HGMP), an attempt to sequence the entire human genome. Although the implementation of new fluorescence-based technology has speeded up and automated the process of DNA sequencing, the method used is still broadly based on the Sanger–Coulson method of chain-terminating nucleotides. It is therefore the detecting methods that have changed, rather than the underlying science. The alternative method of sequencing, chain degradation, has not been so widely employed in modern systems.

The chain-terminating method of DNA sequencing requires single-stranded DNA, because it involves the production of a second complementary strand. Consequently, the DNA to be sequenced is normally cloned into a single-stranded vector such as a plasmid. This is done by cutting out the gene of interest by using nucleases and then ligating it back into the plasmid. By having single-stranded DNA, both to be sequenced and in the vector, it is possible to produce a short oligonucleotide primer which will anneal to the plasmid and allow extension of the DNA by using the gene under investigation as the template for the growing PCR product. The use of a short primer is necessary because most of the DNA polymerases which are used in sequencing reactions need a double-stranded region from which to start synthesis.

A chain-terminating sequencing reaction requires each of the four deoxynucleotides which

Figure 5. The circular plasmid, containing the DNA to be sequenced, short oligonucleotide primers complementary to a known section of DNA, and labeled nucleotides are reacted together. The primer attaches to the plasmid, and then polymerase enzymes extend the primer until incorporation of a dideoxynucleotide terminates chain extension. Denaturing the products, followed by annealing of more primer results in accumulation of artificially produced single strands of DNA complementary to the original template. Overall there will be DNA strands varying throughout the total area of interest in steps of only one base, allowing for step by step sequencing.

can be incorporated into the growing strand. These are dATP, dTTP, dGTP, and dCTP. At this point the original method would require four reactions to be carried out separately. One with the addition of dideoxyATP (ddATP), one with ddTTP, one with ddGTP, and one with ddCTP. These are the chain terminators. Dideoxynucleotides can be incorporated into a growing chain as easily as a deoxynucleotide, but block further strand synthesis. This blockage happens because the dideoxynucleotides lack the hydroxyl group at the 3′-position of the sugar, where the next nucleotide would normally be attached.

When ddCTP is added to the mixture, strand growth will cease when it is incorporated opposite a G on the template strand. However, by adjusting the concentrations of the reagents in the reaction mixture, termination will not always take place at the first template G, because an ordinary dCTP may be added by the enzyme instead. So a number of different fragments of different lengths are produced from this one reaction, each terminated by a ddCTP. When it was normal practice to radiolabel the dideoxynucleotides, they had to be run in separate reactions and run in adjacent columns on a sequencing gel, which was then blotted, autoradiographed, and the bands read horizontally across the gel lanes, with only one band in any position down the gel representing the base at that position on the strand. Sequencing gels are very thin polyacrylamide containing urea to denature the strands.

The modern trend is towards labeling the dideoxynucleotides with fluorescent dyes, each fluorescing at a different wavelength [3]. Besides allowing the sequence reading part of the experiment to be carried out automatically, it also means that the four different reactions can be carried out in one tube, and sequence reading carried out in one lane of a gel [4]. This automation of processes helps to minimize errors. Since the reaction is competitive between deoxynucleotides and dideoxynucleotides, there is a tendency for more low molecular mass products to be formed than high molecular mass ones. There is also a limit to the length of strand which can be accurately sequenced, because as they get longer the percentage molecular mass difference between strands differing in length by a single base becomes progressively smaller. Figure 5 shows diagramatically how cycle sequencing is carried out with a circular plasmid and a thermostable DNA polymerase, so that the reaction can be set up and left to run without intervention until the results are transferred to an electrophoresis system.

Figure 6 shows four lanes of a sequencing gel. As the molecular mass of the fragments increases, towards the top of the gel, they move more slowly and become increasingly difficult

to separate. Using fluorescent dyes allows all the products to be run in the same gel lane. Although the DNA fragments still tend to "bunch" as their molecular mass increases, it is easier to separate the different products because of their different fluorescent wavelengths.

Figure 6. A sequencing gel produced from four separate reactions in a chain termination experiment. Note how these are read sequentially across the gel, and as the molecular mass increases band separation becomes more difficult. By using different colored fluorescent dyes, these reactions can be carried out in the same tube and sequenced on the same track of a gel, or simultaneously on a single capillary electrophoresis device

3.5. Denaturing Gradient Gel Electrophoresis (DGGE)

It is possible to determine the presence or absence of a DNA polymorphism without actually knowing anything about the nature of the polymorphism itself. This is done by using DNA which has been through a PCR to produce enough material to be analyzed. The detection relies on the fact that DNA heteroduplexes, which differ from each other by only a single base pair, not of content, but of type, have measurably differing characteristics that affect the transition from double-to single-stranded DNA. Since single-stranded DNA travels at a slower rate than double-stranded DNA during electrophoresis through polyacrylamide gels, a denaturing gradient will enhance separation.

By having a gradient of a DNA-denaturing agent through the gel, as the similar, but not identical, double-stranded DNA passes down the gel it will melt at different points, at which point the passage through the gel slows down and the original heteroduplexes can be seen to be different. Of course, it is not possible to say in what way the heteroduplexes are different, only that they are. The denaturing gradient can be introduced in a number of ways, such as formamide, urea, or a temperature gradient.

3.6. Single-Strand Conformation Polymorhism

Similar to DGGE, single-strand conformation polymorphism (SSCP) is a method which can be used to detect mutations and polymorphisms without characterizing them. SSCP analysis utilizes the principle that electrophoretic mobility is dependent on size and shape of the molecule and the electric charge. Ideally DNA to be analyzed by SSCP has less than about 400 base pairs. By running a PCR across the area to be tested, enough DNA can be produced for analysis. This is carried out by denaturing the PCR products and then rapidly cooling them. This stops most of the single-stranded DNA reassociating with complementary sequences, but does allow the single-strands to fold into a conformation determined by the sequence itself. A difference of only a single base will alter the conformation and therefore the mobility within the gel, which is of a native, rather than a denaturing, type. Because the conformation can be affected by ion concentration and temperature it is important that the system is highly uniform throughout the proceedure. This means controlling the temperature of the gel during the experiment as well as the solvent and ion concentrations.

3.7. Random Amplified Polymorphic DNA

Random amplified polymorphic DNA (RAPD) is in some ways a misleading name. It allows detection of polymorphisms without any knowledge of the polymorphism, but also without any knowledge of the DNA sequence of the target organism. Indeed, the results can be of limited value because of this, but there are specific applications to which this technique can be put with

great success. RAPD analysis requires the use of a single short oligonucleotide, usually about ten bases long, the sequence of which is chosen at random. The primer will often anneal to genomic DNA during PCR at several different places, giving rise to several bands on subsequent electrophoresis, but if conditions are maintained between experiments the number of bands should remain the same for any individual.

The amplified fragments are highly dependent on the primer sequence and the origin of genomic DNA being looked at. So the results may be of interest, but without further analysis it is not possible to say what form the polymorphisms take or where in the genome they reside. One area of particular interest for RAPD use is in agriculture where it might be necessary to determine the sex of a plant in dioecious species, that is, species for which the male and female flowers occur on different plants. This is useful to stop the planting of more pollinating plants than is necessary, but, as is the case with date palms, until the trees mature and flower it is not possible to determine which trees are male and which female. So by using RAPD analysis differences may come to light between the sexes which can be exploited to determine the sex of the plant while still a seedling.

3.8. Short Tandem Repeat Analysis

Short tandem repeats (STR) are widely distributed throughout the genomes of virtually every higher organism that has been investigated. STRs are arrays of variable numbers of short repeated sequences. They are sometimes referred to as microsatellites since they are very small compared with other satellite DNA. Satellite DNA can be defined as DNA from a eukaryote that separates as a distinct fraction during gradient centrifugation in cesium chloride. The satellite fraction is made up of material of a distinct composition, having a preponderance of A+T or G+C. Some satellite DNA, such as the Alu sequence found in humans, is made up of 300 bp repeats, but in STRs the repeat may be only 1 – 6 bases long. The repeat can be made up of any combination of bases, repeated tandemly.

STRs can be found scattered through the genome in most, if not all, genes. They are located in intron DNA, that is, the interspersed noncoding sections which lie between the exons, or coding sequences. While it is true that introns are not transcribed, it would be incorrect to call them junk DNA. Although not as yet clear why, it seems that introns are necessary to maintain the integrity of the gene. They are also important in evolution, allowing changes to take place within the genome without compromising the metabolism of the cell.

The importance of STR analysis stems from the observation that while some STRs are constant in their repeat number across entire populations, others are highly variable in repeat number. This variability has been found in all species examined. It has also been shown that not all the different alleles occur at the same frequency in any given species. So for a specified STR some alleles will be more common than others, and the distribution frequently approximates to normal, with very small and very large repeat numbers being rarest. Because this is not always the case we can surmise that some other mechanism than simple random processes are affecting repeat numbers of STRs.

It is the inherent variability of STR repeats which makes them of value [5]. By using a PCR reaction across the STR, given that we know the amount of flanking DNA, the fragment can be accurately sized in terms of the number of repeats present. This means that an STR result is expressed not in terms of base pairs, but as a single figure denoting the number of repeats. STR analysis is one of the simplest PCR processes as analysis of results can be carried out with small agarose-gel electrophoresis systems with a sizing ladder in a second lane. The entire gel can then be stained with ethidium bromide and fluoresced with ultraviolet radiation. This approach requires that, unless widely separated in size, only a single STR is analyzed per experiment. The alternative is to make use of automated systems which can cope with several different STRs at a time by using several different fluorescent markers.

STRs have several important uses for the biologist, among which are personal identification and population studies of animal and plant species. This latter function of STR analysis is especially useful in endangered species which exhibit small residual genetic variation. Since STRs are inherited in a strictly Mendelian fashion, with mutation rates generally less than 1 in

10 000 meiotic events, it is possible to determine the level of inbreeding among a group. STRs can also be used to help breeding programs of endangered species by formulating family trees and aiding captive breeding to optimize outbreeding and reduce suppression of fitness by inbreeding. Mutation of STRs most often results in a change in complete repeat number, but this is not always so; single bases are occasionally added in the middle of an STR. It has been suggested that mutation events only serve to increase the size of the STRs, but simply because reductions have not been seen does not mean they do not occur. A continuous increase in STR size would eventually result in physical restraints on the genome, as well as a reduced ability of the cell to function metabolically.

3.9. Single Nucleotide Polymorphism (SNP) Detection

Single nucleotide polymorphisms (SNPs) are represented in the genome as a single base change in a gene, or other DNA being looked at, although they may be considered less informative than other mutations that have several different variants at a single loci. This is because an SNP will normally be biallelic, that is, it is found in either one of two forms only. However, with SNPs being found at a rate across the human genome varying from one every 500 to 5000 base pairs, depending upon which area of the genome is being looked at, there are potentially up to 3×10^6 SNPs in the human genome. This makes them potentially very useful in a range of areas, especially population structure, pharmacogenetics, and complex genetic traits. These last conditions come under the general heading of polygenic and multifactorial inheritance. Examples of this include a surprising range of conditions that have not generally been thought of in the past to be genetically controlled because the number of genes involved and the interaction of these with the environment made it impossible to analyze them by classical genetic techniques. Such conditions as some forms of heart disease and a person's height can be included in complex genetic traits.

SNP analysis is another PCR-based technique. It can be done in a variety of different ways, but the most straightforward, although not the method with the greatest throughput, involves a modification of the sequencing reaction. By creating an initial PCR reaction which runs for approximately 100 bp across the known SNP, sufficient material can be generated for the determination of the nature of the SNP. The next stage uses a primer immediately adjacent to the SNP, and dideoxynucleotides attached to a fluorescent marker. As soon as the next nucleotide is incorporated, which is in the SNP position, the sequence is terminated. When these products are run out on a gel there will be either one fluorescent band of a single color if the individual is homozygous for that SNP, or two bands of different colors if the individual is heterozygous. Although the two products are essentially the same length in base pairs, the difference in mass with the attached dyes is sufficient for them to be separated. If for any reason they are not separable, then electrophoresis mobility modifiers can be used. The first PCR reaction is necessary to produce enough material for the second-round fluorescence to be detectable.

3.10. Mitochondrial DNA Analysis

Mitochondria are small self-replicating subcellular organelles found in the cytoplasm of all eukaryotes. However, the situation is rather more complicated than that. Mitochondria are the site of oxidative phosphorylation, the energy-producing process in eukaryotes, and although they have their own DNA (mtDNA), only a minority of mitochondrial proteins are actually coded on the mitochondrial genome; most are produced by nuclear DNA. So although self-replicating, they are not autonomous. Generally, mitochondria also lack intron sequences within their genes.

The mitochondrial genome varies from about 15 to 20 kb of double-stranded DNA with approximately 50 gene sequences. Mitochondria are generally thought to be inherited only from the maternal line. This has been shown to be incorrect, but in a way which appears contradictory. In humans most of the mitochondrial genome originates from the maternal side: the ovum. However, it has been demonstrated that the mitochondria of the sperm can, and do, enter the ovum on fertilization. The question then arises as to how much of the mtDNA in the

zygote is of maternal origin and how much is paternal in origin. Generally, most testable mtDNA comes from the maternal side, although the sperm does in fact contribute approximately 100 mtDNA genomes to the ovum on fertilization in mammals. Recent studies have shown that there is a selective destruction of the invading sperm mitochondria soon after fertilization.

Studies of three-dimensional reconstructions of cells by using serial sections and electron microscopy suggest that mitochondria either freely associate with each other or are, in any given cell, single entities. In yeasts the mitochondria fuse and bud off from each other quite frequently. Either way, every cell contain several copies of the mtDNA genome which can be tested [6].

Being generally accepted as maternal in origin, mtDNA has the potential to enable us to track through generations via the maternal pathway of inheritance, rather than paternal. This differentiation has great significance in some applications [7].

Mitochodrial DNA comes in the form of a distorted circle, forming a three dimensional structure as it forms hydrogen bonds with itself. In humans mtDNA is generally about 16 570 base pairs long, but it is not the entire sequence which is interrogated when mtDNA is analyzed. It is a short section of highly variable sequence which is looked at, again by PCR.

The reason mtDNA analysis can be so valuable is that unlike nuclear DNA, mtDNA can be found in robust tissues such as bone shafts and hair shafts, which contain no nuclear DNA at all. These tissues, which are tough and resistant to decay, can harbor useful DNA signatures long after the soft tissues have decayed along with the nuclear DNA and become of no use for determining the origin of a sample.

It is the robust nature of mtDNA and relative ease with which it can be copied in a PCR reaction which makes it ideal for investigating ancient samples such as mummified corpses and bones from ancient burial sites. It has also found favor for determining phylogeographic variability in ancient societies. It is not generally necessary to sequence the entire mtDNA because some areas are intrinsically highly variable. One such is the mitochondrial DNA control region with a high variation rate in the 360 nucleotides at the 5′ end of the sequence and to a lesser degree 200 nucleotides at the 3′ end of the control region. Other methods focus on a section of 780 bases of a variable region, which shows a variation rate of approximately 1 %. By concentrating on 12 sites within this region it becomes easier to produce a result and yet maintain the discriminatory power of the test. Mitochondrial DNA analysis has wide applications from familial identification to questioning species origin in food materials.

3.11. DNA Analysis and Bioinformatics

To analyze DNA from any organism increasingly requires fast and reliable computers. The sheer scope of trying to analyze something of the size of, say, the CF gene which spans over 250 kb can be enormous. It would also be extremely difficult without computers to determine whether a sequence has already been defined amongst all the available sequence data. It is often no longer possible to publish database information as tables or lists, the data are just too much for such a manual system to cope with [8].

When looking for something more precise than just sequence data, perhaps data on mutation rates or sequence variability, it is normal to employ a search engine. Although search engines designed for scientists are slowly becoming available, commercial search engines do not well serve the need of scientists. This is essentially because the software uses crawler programs, which index a page, and then jumps to a linked page and goes through the process again. Commercial web pages often have embedded words in HTML code for their page, or use metatags, words invisible but present on the home page.

The unaudited nature of many web pages, both commercial and scientific is also a potential source of problems. If a laboratory sets up a web page that allows publication of any results they have, two things may occur, neither of which is desirable. The first is that erroneous data may be assumed correct, and the second is that correct and valuable data may be overlooked because of the construction of the web page. This second possibility is all the more distressing since the web has a primary aim of disseminating information as widely as possible. A primary feature of DNA analysis in all its forms is the need for different groups to be able to compare their

results with others working in the same area. Without unified databases this is not easily possible and can almost negate the potential value of having data in an electronic form.

Some large databases containing scientific data have the ability to check new data for consistency and contradiction with what is already available. This is a very valuable facility and underlines the need for well edited and definitive databases. Although there are good starting points for searching a particular area of data or data types, there are also some areas where fractioned data are so widely distributed that it becomes extremely difficult to navigate around the subject. There are for example, more than 150 different sites devoted to human mutations. If it were a simple case of the data being widely distributed, that would make the system complicated enough to deal with, but for many years nomenclature also varied so that it was not always entirely obvious if the same mutation was being referred to. Such was the potential for confusion that the Human Genome Organization (HUGO) has created the Mutation Database Initiative which has produced a consensus on nomenclature and computing conventions so that human mutation data can be cross-referenced with other types of data dealing with both other types of human genetic data and also data from other species. Table 3 lists some useful starting points for data mining.

4. Applications of DNA Analysis

One of the earliest applications of DNA analysis came about indirectly, through the agency of gene mapping [9]. Ordering genes on a chromosome or section of DNA can be carried out with no knowledge of the DNA, gene, or gene product, and such maps have been constructed since the early 1900s by breeding experiments. Creation of such maps became ever more sophisticated to the point where a classical map gave way to data regarding the fundamental chemical nature of DNA.

It is not only by sequencing strands of DNA that we can gain information and knowledge from the genetic code. Indeed, even when the entire human genome has been sequenced, this will only be the very first stage in a long story of research. Knowing a DNA sequence alone gives no indication of the reading frame, the length of the gene, and perhaps more importantly, the nature of the protein product. This last point is particularly significant because even if an amino acid sequence is known from a gene, it may not be clear what the final tertiary structure might be, and consequently what the protein does. A good example of this is the characterization of the cystic fibrosis gene, where the gene was known before the gene product or its action. Also, it may not be necessary to know the entire sequence of a gene to produce a valid analysis of its significance and activity.

Cystic fibrosis (CF) is the commonest severe autosomal recessive condition in Caucasian populations. Approximately 5 % of people are carriers, which results in close to 1 in 2000 live births being affected. For a long time it had been possible to predict the probability of carrier status from a simple family history, but it was not possible to be more precise than that for many years, until it became possible to use linkage analysis to associate specific DNA polymorphisms within a family. This is a process in which a marker, that is, any determinable DNA sequence, is usually transmitted with the disease gene of interest by simply being in very close proximity to it. The logic is therefore that if an individual carries the measurable DNA then they will also carry a defective gene.

The CF gene was thus broadly localized to a specific area on human chromosome 7. Later and progressively detailed analysis of the area produced a candidate gene. This was the first time a gene had been sought and found with no knowledge of the protein product for which it coded. It was only found later, after the protein sequence had been determined, that in 68 % of all CF mutations a single 3 bp deletion of the gene, resulting in the loss of a phenylanaline residue at position 508, was responsible for the problem. This mutation was designated ΔF508: Δ for delete, F for phenyanaline, and 508 for the amino acid position. Since then more than 170 different variant mutations of the gene have been described.

To analyze DNA mutations directly in the CF gene a technique can be used which is widely applicable in many areas of DNA analysis and mutation detection. This is the amplification refractory mutation system (ARMS).

Table 3. Useful starting points for finding genetic data on the World Wide Web

Adress	Type Of Data Contained
http://www.gdb.org/hugo/	Home page of Human Genome Organization
http://www.expasy.ch/sprots/sprot-top.html	Home page of the Swiss-Prot database containing data relating to protein function and variation as well as domain structures
http://www.ncbi.nlm.nih.gov/omin	Home page of the database Online Mendelian Inheritance in Man. This is an annotated listing of traits, both diseases and benign polymorphisms which are inherited in a Mendelian fashion. It also contains data regarding mitochondrial dissorders
http://www.incyte.com./index.shtml	This is a commercial database which contains data relating to sequence data of pathogenic organisms, primarily bacteria and fungi
http://www.ncbi.nlm.nih.gov/genbank/genbankoverview.html	A primary depository for human sequence data, currently containing over 4.5 million sequencies covering approximately 3 billion base pairs
http://www.ncbi.nlm.nih.gov/snp/	A primary depository for SNP data, currently containing in excess of 2.4×10^6 SNPs

4.1. General Principles of ARMS Analysis of DNA

A basic ARMS test requires the use of three primers. These cover the area where a known mutation occurs There is one common primer and two other primers, one which we can refer to as the wild type, that is, the normal, fully functional one, and one which includes the mutation. The length of the PCR products is not in itself important, what is important is the sequence at the end of the mutation detection primers. It is for this reason that the sequence of the gene being studied is known.

If a primer has a mismatch at the 3′ end it is most unlikely to produce a PCR product. So by having one wild-type primer and one mutation primer, two PCR reactions will produce either one product (homozygous normal or homozygous affected,) or two products, indicating heterozygous carrier status. This mismatch specificity is maintained by using a PCR enzyme which does not have a 3′ to 5′ proof-reading ability. If an enzyme is used with this capacity to proof read, no sense can be made of the results. Because the PCR reaction is indicating a specific finding, it is usual to run another, unrelated, PCR reaction in the same tube simply to be certain that the PCR has worked; a form of quality control.

Increased specificity of the reaction can be created by introducing deliberate mismatches close to the 3′ end of the primer. The nearer to the 3′ end the introduced mismatch is, the greater the destabilization, so although specificity may be increased, product yield is likely to decrease.

Earlier, there was no way in which PCR products could be differentiated, and individual reactions had to be carried out. With the advent of fluorescent tagging of products this situation has changed. It is now possible, using only a limited number of different fluorescent wavelengths, to carry out ARMS testing in a single reaction for more than 10 different known mutations. This is done by using a combination of different common primers which results in a series of differently sized products. So the fluorescence might appear as red, blue, yellow, red, green, blue, . . . and so on, essentially the same fluorophore is used several times, but has to come within a sandwich of other fluorophores to be accurately sized.

Another technique, now widely used to construct tests for conditions like CF where there are a large number of possible mutations, all resulting in essentially the same phenotype, is the PCR – oligonucleotide ligation assay (PCR – OLA). In this technique multiplex PCR reactions are followed by a multiplex oligonucleotide ligation reaction which is made up of three probes for each biallelic site to be looked at. One probe is common and is labeled with one of three fluorescent dye markers, and the other two correspond to either the normal or mutant variant at that site. These interrogative probes are attached to various different numbers of electrophoresis mobility markers. These are generally penta(ethylene oxide) units, which can be stacked to give products with the same number of nucleotides but widely differing mobility rates. So when the common probe is ligated to the specific probe it results in a unique com-

bination of fluorescence and mobility. By using only four different fluorescent dyes, three for the probes and one as a lane size marker, it is possible to size a large number of different products in the same lane and determine the presence or absence of mutant or normal alleles at each site within the gene.

4.2. Analysis of Dynamic Mutations

A group of human conditions has caused considerable consternation to those trying to define them clearly. These disorders are characterized by dynamic mutations that result in familial transmission, but under some conditions not necessarily in a clearly Mendelian fashion. In those that are clearly inherited in a dominant–recessive way, the age of onset may be extremely variable. This latter state could sometimes be mistakenly associated with closely linked polygenic inheritance or environmental factors. Although relatively few of these conditions have so far been described, they are very important, either because of their frequency or severity. These include Fragile X syndrome, Huntington's Chorea, and Myotonic dystrophy, in which normal dominant inheritance of the condition is modified by a dynamic mutation in the 3′-untranslated region of the gene for myotonin protein kinase.

One of the commonest genetic diseases and certainly the commonest form of familial mental retardation is Fragile X syndrome, affecting approximately 1 in 2500 children. The condition gets its name from the fragile site found at the end of the X chromosome. For many years the only way of diagnosing this condition was cytogenetically, which was inaccurate, time-consuming, and very expensive. Cytogenetic techniques gradually gave way to rather cumbersome pre-screening using molecular methods. Now, however, it is possible to gain a much clearer picture by using PCR in a technique which is equally applicable to other dynamic mutations.

Dynamic mutations are those which are represented not by a change in base composition, but a progressive lengthening of a sequence. This takes the form of progressive expansion of a trinucleotide repeat. In the case of Fragile X it is an increase in the number of polymorphic CCG repeats in the 5′-untranslated region of the gene. The number of repeats varies from about 6 to 55 in normal X chromosomes, but towards the upper limit of 55 the copy number becomes unstable between generations. With over 55 repeats the chromosome is said to have a premutation, and the instability increases dramatically, that is, a dynamic mutation is one where once changed the DNA has an altered risk of further change. When the number of copies exceeds 230 it is a full mutation. It is therefore useful to know how many copies are present in the premutation state. This is done by PCR reactions across the area of the trinucleotide repeat. With very large numbers of repeats in these conditions it may sometimes be necessary to produce products which are more than 2.5 kb long. This can be extremely difficult as the probability of damage to target DNA is proportional to its length. Hence, it is important to extract the DNA mildly and avoid shearing it when using pipettes. An internal control can be used to check the voracity of the PCR reaction. Figure 7 shows the results of sizing the PCR products from three normal individuals, homozygous, heterozygous, and what is commonly referred to as the N+1 heterozygote where there is only one repeat difference between the two alleles. The other peaks represent the ApoE check on PCR and the sizing ladder used to measure the number of repeats.

4.3. Using DNA Analysis to Determine Sex

Humans differ chromosomally between the sexes in that females are the homogametic sex having two identical X chromosomes and males are the heterogametic sex having one X and one Y chromosome. There is a gene which codes for a protein associated with development of tooth enamel called amelogenin. By running a PCR across part of the gene two fragments are generated, one of 212 bases from the X chromosome and the other of 218 bases from the inactive gene on the Y chromosome. These are created by the same primers, so by running the products on a gel there will be two bands from a male and only one band from a female. Although the gene on the Y chromosome is inert, it does not seem to be susceptible to alteration, so this test is now

Figure 7. The automated output from measurement of repeat numbers in Fragile X analysis. The three traces represent heterozygote, homozygote, and N+1 heterozygote. The peak marked ApoE is a check that the PCR has run adequately, and the other peaks are the sizing ladder. This technique is readily extended to other conditions involving this sort of dynamic repeat expansion.
Image courtesy of PE Applied Biosystems

routinely used on forensic samples to determine the sex of the originator of the sample.

Birds are quite different. Here it is the males which are homogametic and females heterogametic. Because of this difference the sex chromosomes are designated Z and W, with males being ZZ and females ZW. There is a highly conserved sequence on the sex chromosomes of birds which differ in only a minor way. By running a PCR reaction across the highly conserved region, enough product is produced for the second stage. The difference between the two is a restriction site which can be cut by the restriction endonuclease *DdeI*. This operates by cutting at the sequence 5′CTNAG3′. The W chromosome produces a 73 bp fragment and the Z chromosome a 104 bp fragment, so there will be either one or two bands on a gel depending on the sex of the bird being tested. Because of the highly conserved nature of the tested sequence, it has been possible to use it in virtually any bird group other than the Ratites (emus, ostriches, etc). Since both sexes of many bird species appear identical, it is important to be able to determine the sex of the birds in captivity, so that breeding programs can make the best use of stocks [10].

4.4. Methods of Personal Identification

Many different methods of personal identification have been developed in the last 25 years on the basis of DNA analysis. The more recently developed ones require more automated equipment but less human intervention, making interpretation of the results far less subjective. The first systems required relatively large quantities of material, usually blood, but as technology progressed so the amount of starting material has decreased, and it is now theoretically possible to determine with a good degree of certainty the generator of a sample. This is especially important in two areas of law: criminal cases and paternity disputes. Although specific methods are used in such cases, this is more for continuity of service and agreement of acceptable methods, rather than one being better than another.

All methods which can discriminate between two sequences can in principle be used to discriminate between two individuals, but the level at which they can be relied upon varies enormously. This reliability can stem just from factors such as inadequate discriminatory power of the test or subjective interpretation of the results, this latter situation being more important in ear-

lier systems that were implemented rather than later ones.

The first methods of personal identification involved the use of mulitlocus (MLP) and single-locus probes (SLP). A sample of native DNA was digested with an enzyme and then run out on a gel. This could then be probed to give several bands per individual in the case of MLPs, or one or two bands in the case of an SLP analysis. The major problem with these techniques is the size of the fragments which are probed. As the measured DNA can run to several kilobases, separation inevitably involves interpretation and agreement on methods of being able to say that a large band does in fact only comprise DNA of a particular type. It is possible that a band that appears to represent 14 kb may in fact be 14.1 kb and therefore different, but not separable, on this scale. It is these sorts of questions which helped to move techniques of personal identification along.

Although the ultimate personal identification method would be to sequence an individuals genome, this is at present not a practical possibility. However, two good methods are available and are routinely used, namely, STR analysis and SNP. Both suffer from an intrinsically low power of discrimination. For example, while any given STR may have 10 or more possible alleles, they will not all be equally common, so a single STR may have a frequency within the population of 1 in 10, that is, 1 in 10 of the population would be expected to have that allele. Some may be even more common. To get around this, a panel of STRs is used, either singly or in one PCR reaction mixture. By multiplying the individual frequencies it is possible to generate a composite value for the probability of finding the total combination of STRs by chance, and therefore a likelihood ratio can be generated for that profile coming from a specific individual. With SNP analysis this procedure is taken slightly further, because for any given SNP the number of possible variants is both smaller and fixed, but the method is essentially the same: production of an accumulated probability by analysis of several different SNPs.

When comparing, say, material from a body with a reference sample, mutation rates are unimportant. But in questions of paternity mutation from one generation to another is a natural consequence of genetic variation. This is one reason why the number of sites looked at is usually much bigger than in situations where a sample is compared directly with an individual [11]. Another reason for this increase is that it gives a greater degree of certainty in the production of a family tree, because only half the loci in the genome of a child comes from the father.

A specialized, and very limited, method which can be employed in personal identification is mtDNA analysis. This procedure is limited because it can link a child to a mother but not to a father, and siblings can not be distinguished by means of mtDNA. It is useful, however, where remains have been found and only mtDNA has survived, for example, after burial or fire. Under these circumstances mtDNA analysis can be used to reunite the remains with the right family.

4.5. Bacterial Contamination of Water Supplies

A practical application of DNA analysis is in detecting coliform bacteria in water supplies. The same techniques can be extended to check for pollution of surface water and beaches by sewage. The importance of this is due to the range of pathogenic microorganisms that occur in fecal material: *Salmonella* (causing typhoid fever), *Shigella* (giving rise to dysentery), and *Vibrio cholerae* (the causal agent of cholera). Another important contaminant is *Legionella pneumophila*, often present in air conditioning units and the cause of legionnaires disease.

Although it has long been possible to detect these organisms, the traditional methods of microscopy and viable plate count are not necessary quantitative methods. Sensitivity is also inadequate with these systems, being approximately 10^4 cells per milliliter, which is far too low for sensitive issues of environmental contamination. A better and more sensitive way of assessing both the presence and quantity of these organisms is to use a PCR reaction coupled with a suitable probe. Sensitivity is now orders of magnitude greater than previously achievable, and detection is possible far beyond the limits required by public health regulations. Thus it is possible to detect as few as 1 – 10 cells per milliliter, which equates to between 1 and 10 fg of DNA depending on the target organism.

For these environmentally important species a panel of very precise probes are used after DNA extraction and PCR of target DNA. The very high specificity of this technique is essential, as there are frequently several different species in a sample, most of which will be benign. Because the detection is based on a presence/absence assay, the PCR products are not run out on a gel, but dot blotted onto a suitable membrane, usually nylon or one of the many proprietary brands available. Once immobilized onto the membrane a probe is used which is labeled at the 5′ end. These dot blots are then probed with the complementary sequence to the target. For *Legionella pneumophila* the probe is based on the macrophage infecting protein (*mip*), and for total coliform bacteria it is based upon a section of the *lacZ* gene of *Escherichia coli*.

4.6. Adulteration of Food Stuffs

Food labeling is not always as accurate as might be supposed, and sometimes accuracy must be checked. Questions which can be asked are, for example, whether a tin of tuna really contains tuna, and are meat products derived from the species that is stated on the label. It is even possible to determine whether pasta is correctly made from hard Durum wheat or from bread wheat.

Given the importance of checking foods for adulteration this is one of the most rapidly developing areas of applied DNA analysis. The constraints are similar to environmental testing, such that it is essential to have an unequivocal standard against which to measure the result. This may seem self-evident, but if you are trying to decide whether a food is what it says it is, there is little point in comparing your results against a standard for which you do not have the provenance, or chain of custody. Mistakes along these lines have happened.

Generally, the methods of checking for authenticity of species origin are based on DNA targets within the cytochrome B gene. This is located on the mitochondrial DNA and has a high species specificity. Although autoclaving is usually regarded as an adequate decontaminating procedure for material being used in DNA analysis involving PCR, this may not necessarily be so. For example, it is possible to determine the species of animal from which a pet food is produced, even though it has been rigorously cooked at high temperature and pressure. Similarly the checking of canned tuna for authenticity is important. This is because "tuna" covers a range of fish in several different genera, so to be sure that a can labelled "skipjack", really is of the genus *Katsuwonus* rather than *Thunnus* (tunny) or *Germo* (the albacore) it becomes necessary to use DNA analysis. In these cases, as with any cooked product, it is generally possible to produce a repeatable result, unless the food stuff has been cooked at high temperature in an acidic liquor, after which results are unreliable and frequently nonexistent.

Whenever food adulteration is suspected, it should be remembered that PCR is a technique of extraordinary sensitivity. Any result must be quantified, and the possibility of accidental contamination must always be considered.

1. Definition of Temperature

Heat is a measure of the energy in a body due to the irregular movement of its molecules or atoms. Temperature is a measure of the internal energy of a body. The internal energy contained in a body is the product of its temperature, its mass, and its specific heat capacity.

2. History of Thermometers

The first physical thermometer, constructed in 1592 by GALILEO utilized the thermal expansion of air. A glass column closed at one end was placed with its open end into a vessel containing a liquid. Variations in temperature altered the air volume, causing the liquid level in the glass tube to rise and fall. The liquid level was therefore a measure of temperature. SANCTORIUS later added a scale to the thermometer. The disadvantage of this type of thermometer was that its reading varied with atmospheric pressure.

In 1660 the first liquid-in-glass thermometer that was not affected by external atmospheric pressure was manufactured for the Duke of Tuscany, Ferdinand II. A glass vessel was filled with a liquid and fitted with a capillary closed at one end. The scale consisted of a maximum value (the highest summer temperature) and a minimum value (the coldest snow). The thermometer was calibrated by RENALDINI in 1694 at the ice point and at the boiling point. The liquid-in-glass thermometers still in use today were developed in 1724 by the Danzig glassblower FAHRENHEIT.

The first Bourdon spring thermometers date from the year 1879. The first liquid-filled Bourdon spring thermometers with a capillary in the form in use today were reported by DREYER-BÜRKNER in 1882.

Bimetal thermometers were invented around 1800 by soldering together two metals with different expansion coefficients. Metal expansion thermometers were manufactured around 1860.

SEEBECK discovered thermoelectricity in 1821; its use for measurement was developed by LE CHATELIER in 1887 and by C. BARUS in 1889. The platinum thermometer – a resistance varying with temperature – was utilized by SIEMENS in 1871. It was further developed by CALLENDAR in 1886 into a precision thermometer, also for measuring higher temperatures.

A principle for noncontacting temperature measurement was proposed in 1880 by CROVA; the radiation densities at two different wavelength were utilized to measure temperature. On this basis LE CHATELIER produced in 1892 the first usable spectral pyrometer.

3. Temperature Scales

As early as 1694 RENALDINI used the melting point and boiling point of water for the calibration of temperatures, since these points are readily reproducible. FAHRENHEIT used as fixed point an ammonium chloride freezing solution, to which he assigned the value 0°, and placed normal human body temperature at 96°.

Around the same time Frenchman Réaumur set the ice point at 0° and the boiling point at 80°. In 1742 the Swedish astronomer CELSIUS introduced the division into 100 degrees, with 0° as the melting point and 100° as the boiling point of water.

In 1887, the hydrogen scale of the Comité International des Poids et Mesures was agreed internationally, and it was decided that a hydrogen thermometer would be the fundamental measuring instrument.

As, according to GAY-LUSSAC (1802), in an ideal gas, the product of volume and pressure increases by 1/273.15 of its initial value per degree, the temperature scale of a gas thermometer can be extended below 0 °C and above 100 °C. According to GAY-LUSSAC, for ideal gases:

$$\frac{(pV)_1}{(pV)_0} = 1 + \alpha t = \alpha\left(t + \frac{1}{\alpha}\right) = \alpha T \tag{3.1}$$

where $(pV)_0$ is the value of the product pV at $t = 0$ °C, $\alpha = 1/273.15$ K and $T = t + 273.15$ K, and T is the temperature relative to absolute zero ($t_a = -273.15$ °C). It is defined as the absolute temperature and was introduced in 1851 by KELVIN. Absolute temperatures are measured in kelvin (K).

These gas thermometers, filled with hydrogen or helium, have their limitations, as even these gases no longer behave as ideal gases at lower temperatures.

The first reproducible temperature scale whose validity was independent of the temperature and of properties of substances was established in 1852 by KELVIN. It is based only on the Second Law of Thermodynamics and is referred to as the thermodynamic temperature scale. Kelvin established for the Carnot cycle a relationship between the initial temperature, the energy flow, and the resulting final temperature. From this relationship, the temperature T and hence also the temperature scale is unequivocally defined as the SI unit of thermodynamic temperature (kelvin). 1 K is 1/273.16 of the thermodynamic temperature of the triple point of water which can be realized with very low measurement uncertainty. The kelvin is also the unit for temperature differences and temperature intervals.

Celsius temperature is defined as the difference between a given Kelvin temperature T and the temperature $T_0 = 0$ K. Temperatures on the thermodynamic temperature scale that correspond to degrees Fahrenheit are expressed in degrees Rankine (°R).

Conversions between the temperature scales can be calculated with the aid of the following equations:

$$T_\mathrm{K} = 273.15 + t_\mathrm{C} = 255.37 + \frac{5}{9}t_\mathrm{F} = \frac{5}{9}T_\mathrm{R} \tag{3.2}$$

$$t_\mathrm{C} = T_\mathrm{K} - 273.15 = \frac{5}{9}(t_\mathrm{F} - 32) = \frac{5}{9}T_\mathrm{R} - 273.15 \tag{3.3}$$

$$T_\mathrm{R} = \frac{9}{5}t_\mathrm{C} + 491.67 = \frac{9}{5}t_\mathrm{K} = t_\mathrm{F} + 459.67 \tag{3.4}$$

$$t_\mathrm{F} = \frac{9}{5}t_\mathrm{C} + 32 = \frac{9}{5}T_\mathrm{K} - 459.67 = T_\mathrm{R} - 459.67 \tag{3.5}$$

where T_K = temperature in K, t_C = temperature in °C, T_R = temperature in °R, and t_f = temperature in °F.

The realization of the thermodynamic temperature scale by means of the Carnot cycle is experimentally laborious. However, the thermodynamic temperature can be determined from all measurement processes that can be derived from the Second Law of Thermodynamics, for example, the general gas equation:

$$pV = nRT_\mathrm{K} \tag{3.6}$$

where p = gas pressure, V = gas volume, n = amount of substance, and $R = 8.314\ \mathrm{J\,mol^{-1}\,K^{-1}}$ (molar or general gas constant).

This expresses a direct relationship between the pressure, the volume and the temperature of an ideal gas. A temperature can therefore be measured by the pressure of a gas. In such a process, no substance-dependent quantities or conversion factors are necessary.

In metrological institutes, the thermodynamic temperature is usually measured with the aid of gas pressure. However, as this measurement method is also relatively difficult and expensive, it was agreed in 1927 to create a practical temperature scale which mirrors the thermodynamic temperature scale as closely as possible. Fixed points (solidification points, triple points, melting points, etc.) of substances are used, and the corresponding thermodynamic temperatures are measured. Based on a large number of comparative measurements performed in the national metrological institutes, the values are then fixed.

By the end of 1989, the International Practical Temperature Scale of 1968, the IPTS-68, had become generally accepted. In 1990, a new scale came into force, the International Temperature Scale, ITS-90. This new scale was necessary because a large number of measurements in various

laboratories in the world showed inaccuracies in the determination of the fixed-point temperatures. The defined fixed points of the ITS-90 are given in Table 1.

Table 1. Fixed points of the ITS-90

	T_{90}, K	t_{90}, °C
Vapor pressure He*	3 to 5	− 270.15 to − 268.15
Triple point H	13.8033	− 259.3467
Vapor pressure H*	17	− 256.15
Vapor pressure H*	20.3	− 252.85
Triple point Ne	24.5561	− 248.5939
Triple point O_2	54.3584	− 218.7916
Triple point Ar	83.8058	− 189.3442
Triple point Hg	234.3156	− 38.8344
Triple point H_2O	273.16	0.01
Melting point Ga	302.9146	29.7646
Solidification point In	429.7485	156.5985
Solidification point Sn	505.078	231.928
Solidification point Zn	692.677	419.527
Solidification point Al	933.473	660.78
Solidification point Ag	1234.93	961.78
Solidification point Au	1337.33	1064.18
Solidification point Cu	1357.77	1084.62

* Calculation of temperature from the vapor pressure/temperature relationship.

For the intermediate values, the temperature scale is defined with the aid of interpolating measuring equipment, for example in the range from − 259 to 961 °C by the platinum resistance thermometer. The thermometer must be constructed in accordance with the requirements of ITS-90 and must be calibrated with the aid of the specified fixed points.

4. Temperature Measurement

Liquid-in-Glass Thermometers. In the liquid-in-glass thermometer the thermal expansion of a liquid is used for determining the temperature. The liquid is placed in a thin-walled glass vessel which is attached to a capillary. The capillary carries a scale from which the temperature can be read. Glass thermometers are used today in domestic and laboratory applications.

Mechanical Dial Thermometers. Mechanical thermometers convert the thermal expansion of gases, liquids, or metals into a change in the position of a pointer. The temperature scale is positioned locally but may also be located a few metres from the measurement point. Compared with glass thermometers, mechanical thermometers are unaffected by vibrations and contain no substances which could endanger the environment. The thermometers operate without any external energy, permit the switching of limit contacts, and subject to the appropriate approval can be used in explosion-hazard areas. They offer long-term stability and, unlike electrical thermometers, are unaffected by electromagnetic influences.

The most widely used mechanical thermometers are the gas-pressure and the liquid-filled Bourdon thermometers and bimetal thermometers.

Gas-Pressure Bourdon Thermometer. The general equation of state of an ideal gas is:

$$\frac{pV}{T_{\mathrm{K}}} = \text{const.} \tag{4.1}$$

where p is the pressure of the gas, V the volume, and T_{K} the temperature of the gas in kelvin.

If the temperature of a gas contained in a closed system is increased (e.g., in a cylinder with a sliding piston), the product pV increases correspondingly. Assuming an isobaric process (temperature change at constant pressure) the following relationship applies to the volume:

$$V_{\mathrm{T_{new}}} = \frac{T_{\mathrm{new}}}{T_{\mathrm{old}}} V_{T_{\mathrm{old}}} \tag{4.2}$$

where $V_{\mathrm{T_{new}}}$ is the volume at the new temperature, T_{new} and $V_{\mathrm{T_{old}}}$ = volume at the old temperature T_{old} in K.

Replacing T_{new} by $T_{\mathrm{old}} + \Delta T$ (ΔT = temperature increase of the gas) gives

$$V_{\mathrm{T_{new}}} = \left(1 + \frac{\Delta T}{T_{\mathrm{old}}}\right) V_{T_{\mathrm{old}}} \tag{4.3}$$

Equation (4.3) describes in idealized form the process in a gas-pressure thermometer: the volume of a gas (usually nitrogen) increases in proportion to the temperature.

The gas-pressure Bourdon thermometer (Fig. 1) consists of the actual temperature probe, which is a metal vessel containing the gas volume. As the gas expands with increasing temperature it passes through the capillary to the elastic measuring element (Bourdon tube). The

inflowing gas causes the Bourdon tube to expand. This movement is transferred to a pointer, the position of which indicates the temperature on a scale.

Figure 1. Gas-pressure Bourdon thermometer
a) Temperature probe; b) Capillary; c) Bourdon tube; d) Pointer; e) Scale

The measuring range of gas-pressure Bourdon thermometers is between −100 and +600 °C, their accuracy is Class 1 (according to EN 13190). In practice the upper limit of the range should not be too low, otherwise excessive pressurization of the gas is required.

Part of the gas is always inside the capillary rather than the measuring element and is therefore not exposed to the temperature of the measurement location. The ambient temperature influences this part of the gas and therefore the result of the measurement. The ambient-temperature effect, expressed as percentage of range for gas-filled thermometers, referred to 23 °C is 0.1 %/K (max.) for housing and 0.005 % m^{-1} K^{-1} (max.) for the capillary.

Liquid-filled Bourdon Thermometer. The volume change of a liquid with increasing temperature is described by the following equation:

$$V_{T_{new}} = (1 + \gamma \Delta T)\, V_{T_{old}} \tag{4.4}$$

where $V_{T_{new}}$ is the volume after temperature change by ΔT in K, $V_{T_{old}}$ the volume before temperature change, and γ the volumetric expansion coefficient in K^{-1}.

The relationship indicated in Equation (4.4) is an idealized description of the process in a liquid-filled Bourdon thermometer: a liquid volume (petroleum or Diphyl KT) increases proportionately with temperature. The construction of the thermometer is similar to that of the gas-pressure Bourdon thermometer. Liquid-filled Bourdon thermometers cover the range −40 to +350 °C; their accuracy is Class 1.5 or 2 (according to EN 13190).

The ambient-temperature error, expressed in percentage of range, for liquid-filled Bourdon thermometers, referred to 23 °C is 0.15 %/K (max.) for the housing, and 0.015 % m^{-1} K^{-1} for the capillary.

Bimetal Thermometers. Metals expand with increasing temperature, like most solid bodies. The expansion depends on the temperature and on the type of metal:

$$l_{new} = l_{old}\,(1 + \alpha\, \Delta T_K) \tag{4.5}$$

where l_{new} is the length of the metal after temperature increase by ΔT_K, l_{old} the initial length of the metal, and α the linear expansion coefficient of the metal.

If two metals with different linear expansion coefficients are combined into a bimetallic strip and exposed to a temperature rise, the strip deforms into a curve. This effect is utilized in the bimetal thermometer.

The temperature-sensitive component consists of a spiral or coiled spring which is wound from a bimetallic strip. A temperature change causes the spring to close up or to unwind. In the simplest case the spring is fixed on the outside and carries a light plastic pointer on its inner end. Other arrangements with an immersion tube permit some separation between sensing element and indicator; the immersion tube contains a spindle which is rotated by the bimetallic coil and transmits this rotation to a pointer at the end of the immersion tube.

The range of these thermometers is between −80 and +500 °C. Their accuracy conforms to Class 1 or 1.5 (according to EN 13190).

Electrical Thermometers. In industrial processes the measurement site is often remote from the point of indication. Often, the temperature reading must be processed in controllers or recorders. Such applications are unsuitable for directly indicating thermometers and require types which convert the temperature into an electrical signal. The most widely used sensors of this type are the platinum resistance thermometer and the thermocouple.

Platinum Resistance Thermometer. The electrical conductivity of metals is based on the mobility of conduction electrons. The movement of electrons is, among other parameters, dependent on temperature. Increasing the temperature causes the oscillations of the atoms to increase, raising the overall resistance of the metal. This effect is utilized in the platinum resistance thermometer (Fig. 2).

Figure 2. Characteristic of a platinum sensor Pt100 (EN 60751)

Platinum resistance thermometers are defined by EN 60751 according to different tolerance classes (Fig. 3).

Temperatures can also be measured with resistors whose variation with temperature is not standardized. They involve a very inconvenient calibration of the electronics and are not fully interchangeable, so that they do not play an important part in industrial temperature measurement.

Figure 3. Tolerances of the platinum resistance thermometers (EN 60751)

In the platinum resistance thermometer, a defined and constant current I is passed through the element, and the resulting voltage is used to deduce the resistance and therefore the temperature. This arrangement forms a connection in a *two-wire circuit*. The measured voltage is given by:

$$U = (R_{\mathrm{Pt}} + 2\,R_{\mathrm{L}})\,I \tag{4.6}$$

where U is the measured voltage, R_{PT} the resistance, R_{L} the lead resistance, and I the current.

The measured voltage, the measure of temperature, includes twice the lead resistance. Even where this is allowed for in the arrangement of the measuring system it is not possible with this type of circuit to compensate errors due to varying lead resistance (temperature changes of the leads).

For this reason the *three-wire circuit* (Fig. 4) has an additional lead connected to one end of the measuring resistor. The measurement consists of the voltage at this point (potential against 0 V), and the total voltage across the sum of measurement resistor and the lead resistances.

The total voltage in the evaluation electronics is given by:

$$U = (R_{\mathrm{Pt}} + 2\,R_{\mathrm{L}})\,I \tag{4.7}$$

Figure 4. Platinum resistor in a three-wire circuit arrangement

The voltage at the third lead against 0 V amounts to:

$$U_H = I R_L \tag{4.8}$$

U_H = voltage against 0 V at the third lead.

To obtain the actual voltage at the sensor the electronics deducts $2\,U_H$ from U.

The *four-wire circuit* involves two additional leads which are used to measure the voltage directly at the measuring element. Variations in the lead resistances then have no influence on the measurement.

When using resistance thermometers in a two-wire circuit, any change in the temperature of the leads results in alterations in the measured temperature since the altered lead resistance forms part of the measured resistance. If this influence is too large it is advisable to operate the resistance thermometer in a three- or four-wire circuit.

The resistance of the platinum sensor has certain nonlinearities with temperature. Controllers and recorders manufactured by JUMO therefore incorporate linearization tables which can be activated when a platinum sensor is connected.

Measuring resistors are supplied in different designs:

The *ceramic temperature sensor* has a platinum coil of 0.010 to 0.035 mm diameter wire arranged in two bores of a ceramic tube. The bores are filled with alumina powder to secure the winding and to improve heat transfer. The winding has no direct contact with the housing. On changes in temperature the platinum winding can expand freely and experiences only very small forces, and this results in a sensor with a high long-term stability. The sensor has a very wide temperature range of − 200 to + 800 °C (sometimes up to 1000 °C) but is very expensive due to the large amount of manual work involved. Dimensions: diameter 0.9 – 5.0 mm, length 10 – 35 mm.

In *glass temperature sensors* the platinum wire is wound on a glass former and hermetically sealed in glass, permitting direct use in a fluid. The sensor is very resistant to shock and can be used at temperatures between − 200 and + 400 °C; it is also very expensive because of the large amount of manual work. Dimensions: diameter 0.9 – 5.0 mm, length 7 – 55 mm.

The *foil temperature sensor* consists of two polyimide foils enclosing a platinum wire. This flexible temperature sensor is used for measurement on surfaces, pipes, and tools in the temperature range − 80 to + 180 °C. The sensor has a high dielectric strength (up to 2 kV), but because of the mechanical loading its stability is less than that of wire-wound temperature sensors. The large amount of manual work again results in a high price. Dimensions: length 50 mm, width 21 mm, thickness 0.4 mm.

The sensor with the largest market share is certainly the *thin-film resistor* (Fig. 5). The sensor has a permitted temperature range of − 70 to + 600 °C. Produced by large-scale manufacture, the low-cost thin-film measurement resistor has a wide range of applications (laboratory, industrial measurement and control, medicine, white goods, cars, etc.). Dimensions: length 2.3 – 10 mm, width 1.5 – 2 mm.

Figure 5. Thin-film measurement resistor

Long-term stability of resistance thermometers is largely influenced by the conditions of use and structural features. Temperature cycling between upper and lower temperature limits involves much more stress on all components than a steady load. Ceramic sensors exhibit very stable long-term behavior, since mechanical coupling is limited by embedding the wire winding in powder.

With glass and thin-film sensors there is very close coupling between the temperature-dependent platinum and the glass or ceramic substrate. This produces changes in the crystal structure of the platinum and results in changes in its resistance. In the manufacture of glass sensors this problem is met by selecting a glass with approximately the same temperature expansion coefficient as platinum. In addition the sensors are artificially aged. Intensive research and development has led to the development of thin-film resistors which also offer good long-term stability.

A further error in temperature indication may be caused by insufficient resistance of the insulation. Particularly in ceramic sensors, the insulation resistance decreases with increasing temperature above 600 °C. Insufficient insulation resistance may also be caused by ingress of moisture, which must be prevented by appropriate measures.

Temperature measurement with a resistance thermometer involves the passage of a current; this produces heating of the sensor and therefore an increase in the indicated temperature. This self-heat depends on the measurement current, the basic resistance of the temperature sensor, and on how readily heat can be dissipated.

The connecting wires of resistance thermometers often consist of silver as internal connections which are extended by copper or nickel. The thermal voltages produced at these changeover points only cancel out if they are at the same temperature. With unbalanced voltages the resulting thermal voltage is interpreted by the evaluation electronics as a voltage drop, resulting in a measuring error. These thermal voltages can be completely suppressed by operating the resistance thermometer with alternating current instead of direct current.

The Thermocouple. If a metal is heated at one end, the heat supplied increases the mean velocity of the free electrons. The electrons drift from the warmer to the cooler region and form a negative charge there. A voltage is generated between the cold and the warm regions inside the metal body. To measure this voltage a second conductor of the same material must be placed in contact with the warm end. A similar charge is produced inside the second conductor so that the potential difference is 0 V. If, however, a different metal is used whose electrical conductivity is poorer than that of the first metal, the reduced number of electrons at the cold end results in a lower negative potential. The difference between the two potentials can be measured as a voltage between the two ends. The negative pole of the thermocouple appears at the metal that has the higher electrical conductivity.

From the large number of metal combinations a few have been selected in EN 60584 and standardized with respect to their voltage calibration and permitted tolerances. Such thermocouples are therefore fully interchangeable.

EN 60584, Part 2, defines the tolerances in three classes. Classes 1 and 2 apply to the range above − 40 °C while Class 3 is essentially for negative temperatures down to − 200 °C.

Figure 6. The thermocouple measurement chain

Figure 6 shows the connections to a thermocouple. Thermocouples are frequently located at some distance from the measuring device; since the thermocouple is made from expensive materials, the connection to the measuring instrument is made through a compensating cable which has the same thermoelectric properties as the actual thermocouple. The voltages at the changeover points compensating cable Fe – Cu and Cu – compensating cable CuNi are added together to form the thermal voltage which would be produced by a direct connection of the two compensating leads. The voltameter therefore measures the thermal voltage of the Fe – CuNi thermocouple at the measuring point (T_1) minus the thermal voltage at the changeover to copper (T_2). The voltage measured by the instrument is

a measure of the temperature difference between T_1 and T_2; the electronics must therefore measure the temperature T_2 and add it to the temperature difference determined from the thermal voltage.

Foreign atoms which become absorbed in the thermocouple material influence the binding force of the electrons and produce a change in its thermoelectric properties; the thermocouple calibration starts to drift. To limit this effect, as well as other external influences the thermocouple is placed inside a protection tube or is embedded together with an oxidic insulating material inside a metal sheath (mineral-insulated thermocouple).

Selection criteria for different thermocouples, principally the use temperature and the magnitude of the thermal voltage, are given in the following:

Cu – CuNi	not widely used
(Cu – Con)	oxidizes already above 200 °C
	copper: high thermal conductivity favours heat-conduction errors
Fe – CuNi	widely used (low cost)
(Fe – Con)	used in the low and medium temperature range
	iron becomes brittle a sulfur-containing atmospheres
	alson used as mineral-insulated thermocouple
NiCr – CuNi	used in the low-temperature range because of its large thermal voltage
(NiCr-Con)	widely used in the USA
Ni – CrNi	used above 600 °C
	good long-term stability (ten times better than Fe – CuNi)
	maximum temperature as mineral -insulated thermocouple: 1150 °C
NiCrSi – NiSi	can be used up to 1300 °C
	as mineral-insulated thermocouple with suitable sheath material also stable at high temperatures
	has only been on the market for a few years
Noble metals	used only at temperatures above 800 °C
	high cost
	appreciably better stability than other thermocouples
	small basic tolerances

The thermal voltage may be highly nonlinear with temperature; controllers and recorders manufactured by JUMO therefore incorporate linearization tables which can be activated when a thermocouple is connected.

Terminals and compensating cables are often made from materials with different thermal properties than the actual thermocouple. Any temperature gradient at these transition points produces an additional thermal voltage which introduces errors into the measurement. As mentioned above, the cold junction temperature has to be added by the evaluation electronics. If this is measured incorrectly the measurement is falsified to the same extent. With fast-response thermocouples the thermocouple wire is often welded to the protection tube. This may result in circuit loops to electrical loads or other thermocouples. A remedy consists of providing insulation in the supply to the amplifier and between the measurement inputs.

The resistance of insulating ceramics decreases rapidly above 1000 °C. In spite of the insulated construction, the supply voltage can then leak into the measurement line. Contamination of a thermocouple alters its thermal properties. It introduces permanent errors into the measurement and reduces the lifetime.

Comparison of Resistance Thermometers and Thermocouples. Table 2 lists the main distinctions between resistance thermometers and thermocouples.

Figure 7. Thermometer fittings for resistance thermometers and thermocouples to DIN 43770 Specification

Construction of Electrical Thermometers. In addition to the almost innumerable number of special versions there are a number of types in which all components are completely described by DIN specifications (Fig. 7). Such a thermometer is of modular construction; it consists of the measurement resistor or thermocouple, the protection tube, the terminal head and the internal terminal base, as well as possibly flanges, clamping devices and movable sleeves. The actual temperature transducer or sensor is that part of the thermometer which is directly

Table 2. Comparison of resistance thermometers and thermocouples

Criterion	Thermocouple	Resistance thermomoeter
Range	− 270 to + 2800 °C	− 220 to + 850 (1000) °C
Overall system accuracy	± 0.75 % of measured temperature	± 0.5 % of measured temperature
Stability: aging error per annum	a few °C	± 0.5 °C
Insulation resistance	important (insulated construction)	very important (large effect)
Size (without protection tube)	relatively small size	relatively large size
Cold junction temperature	required	not required
Characteristic	often strongly nonlinear	slightly nonlinear
Manufacture	relatively simple	relatively complicated

affected by the temperature and which contains the temperature-sensitive part of the thermometer.

General Aspects of Temperature Measurement with Electrical Thermometers. One of the most important errors in temperature measurement with electrical thermometers is a consequence of the thermal inertia of the sensor. If there is a change in the temperature of the medium, after a certain finite time the temperature of the medium and that of the thermometer equalize as a result of the flow of heat.

If the thermometer is considered to be a homogeneous mass m with very good thermal conductivity and surface area A, this can be represented by a first-order curve. The response $\vartheta(t)$ of such a "theoretical thermometer" to a step change $\Delta\vartheta$ is given by the equation:

$$\vartheta(t) = \Delta\vartheta\left(1 - e^{\frac{t}{T}}\right) \tag{4.9}$$

where

$$T = \frac{1}{\alpha}\frac{m}{A}c \tag{4.10}$$

c = specific heat capacity of the sensor material, α = heat-transfer coefficient.

After a step change in the temperature of the medium, the subsequent temperature changes of the sensor take the form of a pure exponential function, the shape of the curve being determined only by the time constant T. From Equation (4.10) for the time constant, certain properties necessary for a rapid response of the sensor can be deduced. A small time constant (and thus a rapid response of the sensor) results from:

- Good heat transfer between the medium and the sensor
- Low mass of the sensor
- Large heat transfer surface area
- Small heat capacity of the sensor

When measuring with electrical thermometers, it is often not realized that the heat transfer coefficient of a gaseous medium is considerably lower than that of a liquid. Therefore, the response time of a thermometer used for measuring the temperature of gases is considerably longer than that for liquids.

In practice, electrical thermometers give curves of higher order. This is especially the case if the sensor element is inside a protective tube. The higher order is the result of the series arrangement of the many individual elements (steel, air, silica sand, sensor) that are separated by thermal resistances.

To compare electrical thermometers with respect to their dynamics, manufacturers determine the response to a step change under defined conditions (medium, flow rate, etc.). The dynamic characteristics are then determined from the delay curve of the measured temperature. The times are usually determined at which the measured temperature rises to 50 % ($t_{0.5}$) and 90 % ($t_{0.9}$) of the step change in the temperature of the medium. These response times are usually given for various media (water, oil, etc.).

It is acceptable to regard a thermometer as having a first-order curve in order to give an approximation of its behavior. However, as already mentioned, electrical thermometers have curves of higher order, so that a time constant cannot be determined and is therefore not quoted by manufacturers.

A thermometer is rarely used for the measurement of ambient temperature. The measurement point is generally warmer or colder than the environment. It is then possible for some heat to be conducted through the thermometer, leading to incorrect measurements. The sensor is connected through cables which are good con-

ductors of heat and which form a thermal link. This problem can be overcome by good thermal connection to the protection tube while at the same time decoupling the connection cables. The probe housing should incorporate as much insulation as possible. The immersion depth of the thermometer in the fluid as well as the flow velocity of the fluid should be chosen to be adequately large.

The Radiation Pyrometer. Every surface whose temperature is above absolute zero emits electromagnetic radiation (thermal radiation) in the wavelength range $0.1 < \lambda < 1000\,\mu\text{m}$. Measuring devices that can determine the temperature of a body from its thermal radiation are known as pyrometers.

If a radiation flux impinges on a surface, it is partly reflected, partly absorbed, and partly transmitted. The relevant proportions are defined as follows:

$$\text{Reflectance} \quad r = \Phi_\text{r}/\Phi \leq 1 \tag{4.11}$$

$$\text{Absorbtance} \quad \alpha = \Phi_\text{a}/\Phi \leq 1 \tag{4.12}$$

$$\text{Transmittance} \quad \tau = \Phi_\text{tr}/\Phi \leq 1 \tag{4.13}$$

The magnitude of these fractions depends very much on the bodies being irradiated. For a so-called black body, all the radiation is absorbed and converted into sensible heat. However, a body does not only absorb radiation, but also emits it because of its own temperature. The black body or the black emitter has the highest capacity to emit. The ratio of the radiation emitted by a nonblack body to that emitted by a black body is termed the emissivity. The emissivity depends on the surface temperature and the wavelength of the radiation. According to Kirchhoff, the emissivity is the same as the absorptance α. Bodies for which the emissivity is independent of the temperature and the wavelength are known as gray emitters. However, real bodies should normally only be termed gray emitters over a limited spectral range.

The radiation flux is defined as the specific-spectral emission Φ of the black body relative to wavelength and surface area:

$$M_{\lambda b} = \left[\frac{\text{W (power)}}{\text{m}^2\,\text{(surface area)} \cdot \text{m (wavelength)}}\right] \tag{4.14}$$

According to Planck's Law, the specific-spectral emission $M_{\lambda\text{b}}$ of a black body is a function of temperature and wavelength (see Fig. 8).

Figure 8. Specific spectral emission of a black body as a function of wavelength

However, no body emits as an ideal black body, and the emission of a nonblack body is therefore less than that of a black body. The emission of a body is given by:

$$M_\lambda = \varepsilon_\lambda M_{\lambda s} \tag{4.15}$$

where ε_λ is the spectral emissivity.

If the spectral emissivity of a body is known and if one considers the radiation in a narrow wavelength band of the spectrum, the temperature of the body can be found from its radiation and from Planck's Law.

It is often desired to determine the surface temperature not from the radiation in a particular spectrum but from the sum of the total radiation (all wavelengths). The Stefan – Boltzmann Law leads to the following equation:

$$M_s = \varepsilon C_s \left(\frac{T_\text{K}}{100}\right)^4 \tag{4.16}$$

where T_K is the temperature in Kelvin and C_S a proportionality constant.

The above physical law is utilized for remote temperature measurement.

1. Introduction

1.1. Definition and Origin

Cork is the suberous covering (suberose parenchyma, or bark) of the species *Quercus Suber* L., commonly known as the cork oak. Cork is composed of an aggregate of cells, about 42 millions per cubic centimeter, which have five layers walls. Cork is a very light material, elastic and flexible, and impermeable to gases or liquids. It is imperishable and a good electric, thermal, sound, and vibration insulator [1].

The cork oak grows mainly in the Mediterranean zone, especially where there is an Atlantic influence, and Portugal produces more than half of the world's cork. The cork tree has a natural reproduction by acorns or, more frequently by producing shoots [2]. The cork oak is a dicotyledon of the family Fagaceae, and it is part of the genus Quercus having dozens of varieties [2].

All the trees have a thin layer of cork in their bark but *Quercus suber* is the only one where the cork forms a several centimeters thick layer around the trunk, with the function of insulating the tree from heat and loss of moisture and protecting from damage by animals and fire. Cork regenerates after each stripping.

Today cork products are used for thermal insulation in refrigerators and rockets, acoustic insulation in submarines and recording studios, seals and joints in woodwind instruments and combustion engines, as energy-absorbing medium in flooring, shoes, and packaging, and of course as stoppers [3]. The utilization and processing of commercial cork depend very much on its structural quality [4].

1.2. History

The cork oak dates from the Oligocene stage of the Tertiary Period. It is thought that it was disseminated from the region covered by the Tyrrhenian Sea and that it migrated to the Iberian region in the Miocene stage [2].

Strangely, the first peoples to put cork to what it became after were not of these regions. In ancient China (3000 B.C.) cork was used for fishing buoys, and amphoras were found closed with cork in excavations in Pompeii and in tombs in Egypt [5]. In ancient Greece the bark of the cork was used to make buoys for fishing nets, sandals, and stoppers for wine and olive oil vessels.

In the early days of Portuguese nation, cork was used in building (including shipbuilding). By the 14th century it was already an economic asset of national importance in Portugal. The great step forward for the generalized use of cork was taken by the French Benedictine monk Dom Pérignon (1639 – 1715), proctor of the Hautvillers' Abbey who developed champagne production. He observed that the wooden stoppers wrapped and soaked in olive oil, that were used for the containers holding sparkling wine often jumped out. So he used cork stoppers with surprisingly good results and soon cork became essential for wine producers [2].

In 1750 in Angullane (Gerona), close to the French border, the first stopper factory opened, marking the beginning of cork industry, which then expanded to Portugal. Around 1770, when Port Wine trade had begun to flourish, the cork stopper became indispensable.

The real boom of the cork industry began in the last quarter of the 19th century. In 1915 Portuguese cork oak forests covered between 300 000 and 470 000 ha and nowadays encompass more than 700 000 ha. In 1927 Portuguese annual cork production was 16 000 t and is now about ten times higher [2].

At the end of the 19th century, an American manufacturer of lifejackets accidentally found that it was possible to produce agglomerated cork. This was the beginning of a new world of opportunities in which waste cork and cork previously thought to be of no commercial value could also be used [6].

In the first half of the 20th century, the world cork market was controlled by a handful of multinational companies. However, their productive investment was minimal, especially in Portugal and Spain. They worked in these countries through small offices that acted as purchasing centers for the raw materials and some manufactured goods, that were channeled to other centers for processing and distribution. In the 1960s, Portuguese companies started to invest in modern factories and today Portuguese cork industry processes more than 2/3 of world's cork [1]. Nowadays Spain is the second world cork producer and transformer.

1.3. Morphology

1.3.1. Microscopic Aspects

Cork has an open structure, which is made up of cells of 20 to 30 millionths of a millimeter in size, forming the suber and the rays. The cell lumen contains mainly nitrogen. A thickness of 1 mm corresponds to about thirty layers of cells, 1 mm^3 has about 20 000 – 40 000 cells [2,7].

Cork tissue is made up of dead micro-cells, generally 14-sided polyhedrons, slotting in one against the other. The contents of newly formed cells disappear during growth and the subsequent suberization process of the membranes, which imparts the completion of communication with the plant living tissues.

The cells are staked in long rows with thin walls. The radial section also shows five, seven and eight sided shapes [3]. Cells walls are covered with very thin layers of waxes and suberin which make them impervious to air and water and resistant to attack by many acids. The cell walls are conjugated. The cork cells are closed hexagonal prisms (average) stacked in rows so that two cells share the hexagonal faces, and the rows are staggered so that the membranes forming the hexagonal faces are not continuous across rows (see Fig. 1).

The cellular structure of cork is significantly influenced by temperature; upon heating cork cells expand and the cell walls stretch, attaining their maximum volume (twice the original volume) at 250 °C [8].

The intracellular layers comprise five parts: two made of cellulose, a further two of hard matter with impermeable components (suberin, waxes) and a final ligneous part, whose function is to maintain structure and rigidity [1].

Figure 1. Diagram of cork tree and cork with axis system

The cell walls have a thickness of about 1 – 2 µm, a height of about 10 – 45 µm and a hexagonal face edge of about 20 µm (see Fig. 2). The density of cork is related to that of the cell wall material, which is close to 1150 kg/m^3 [3,7]. The thickness of cork cells is lower in spring and greater in autumn. The cell height has also a minimum value in autumn.

Figure 2. Micrograph of cork cells and corrugated cell showing dimensions

The unevenness of membrane thickness, height and diameter of the cells can affect the cork's mechanical and physical properties, namely compressibility and elasticity. The prismatic shape of the cells makes the cork anisotropic [7].

When cork deforms, cell walls bend and buckle, giving resilience. Tensile deformation along the prism axis unfolds the corrugations, straightening prism walls. Compressive deformation folds the corrugations up to a certain point where the cells collapse completely. Axial compression produces almost no lateral expansion, due to the fact that cells fold [3,7].

1.3.2. Macroscopic Aspects

The cork tree has a remarkable capacity to create a suberous tissue from its inner bark. The external productive layer or phloem grows in the direction of the bark and produces cork [6]. As the phellogen is only active for 6 – 7 months each year, the differences in cell size and the thickness of cell membranes between cork produced in different year seasons leave discernible rings (growing rings), which change from 1.5 to 4 mm in thickness on average, mainly according to the nature of the soil, climatic conditions, and vitality of the tree [6]. Younger trees produce usually very porous and cracked cork and old and aging trees form thin cork.

Natural cork contains lenticels, which are tubular channels that connect the outer surface of the bark to its inner surface allowing oxygen into and carbon dioxide out from the new cells that grow there.

The life cycle of the cork oak produces three qualities of suberose tissue: virgin cork, reproduction cork from the second stripping, and reproduction cork from subsequent stripping. *Virgin cork* is the suberose tissue extracted for the first time (usually when the tree is 25 years old), it is hard and has an irregular structure. *Summer virgin* is the cork extracted from a level above the previous extraction. *Winter virgin* is the virgin cork from the pruned branches, containing fragments of fiber and ligneous tissue. The first *reproduction cork* (taken at least nine years later) is more regular than virgin cork but does not yet have quality enough for cork stopper production [1]. Only the second reproduction cork can be used for cork stoppers. All the other types of cork can be used for agglomerates.

The thickest suberose layer is generally formed in the growing cycle subsequent to cork extraction and then the cork produced diminishes progressively year after year.

Porosity is a consequence of the lenticels, orifices or pores in the tissue. Porosity depends on the area occupied by lenticular channels cut tangentially. If porosity is excessive (>4 %) the economic value of cork may decrease for some applications [1].

1.4. Chemical Composition

The chemical constitution of cork depends on factors such as geographical origin, climate and soil conditions, genetic origin, tree dimension, age and growth conditions [1,9,10].

According to the proposed model [11], the cellular structure walls of cork consists of a thin and lignin-rich middle-lamella primary wall, a thick secondary wall made up from alternating suberin and waxes lamellae and a thin tertiary wall of lignin and polysaccharides. Studies on chemical composition show that the secondary wall is lignified and therefore may not consist exclusively of suberin and waxes [9]. Further information on suberin structure has been obtained from solid-state ^{13}C NMR spectroscopy studies, showing that the aliphatic chain of suberin is spatially separated from lignin and polysaccharides [12].

The main chemical constituents of cork can be divided in five groups:

Suberin	33 – 50 %
Lignin	12.6 – 30 %
Cellulose and polysaccharides	12 – 20 %
Waxes	3.5 – 7.9 %
Tannins and other phenolic substances	6 – 7 %

1.4.1. Suberin

The structure of suberin in cork is not yet fully understood. It has been proposed that suberin consist of a polyester structure composed of long-chain fatty acids, hydroxyfatty acids and phenolic moieties, linked by ester groups, as shown in Figure 3 [13].

Suberin is insoluble in all solvents but can be depolymerized by cleavage of the ester linkages by alkaline hydrolysis, alcoholysis, transesterification (catalyzed by soda, alkoxides or boron trifluoride) or reduction. The aliphatic components of suberin include fatty acids, fatty alcohols (mainly C_{20}, C_{22}, and C_{24} alcohols) and glycerol. Glycerol (**1**), is present as component of esters of suberinic acids [14–18].

The fatty acids include monoacids, α,ω-diacids and ω-hydroxyacids, which can have different functionalities including double bonds, vicinal hydroxy and epoxide groups. The most

Figure 3. (rotated) Schematical structure of cork suberin

important acids are 9,10-dihydroxyoctadecanedioic (phloionic acid) (**2**), 18-hydroxyoctadec-9-enoic (**3**), octadec-9-enedioic (**4**), docosanedioic (phellogenic acid) (**5**), 22-hydroxydocosanoic (phellonic acid) (**6**), and 9,10,18-tridihydroxyoctadecanoic acids (phloionolic acid)

Table 1. Composition of suberin monomers of cork (%)

Compounds	Structure	Content in cork, %
Aliphatic		
Propane-1,2,3-triol (glycerol) **1** [*56-81-5*]	$HO\text{-}CH_2\text{-}CH\text{-}OH\text{-}CH_2OH$	2.0 – 7.0
1-Alkanos (C_{18} – C_{28})	$CH_3(CH_2)_nOH$	2.3 – 2.8
Alkanoic acid (C_{16} – C_{28})	$CH_3(CH_2)_nCOOH$	1.3 – 10.0
α,ω-Alkanodioic acids (C_{16} – C_{26})	$HOOC(CH_2)_nCOOH$	6.2 – 12.3
α,ω-Alkenodioic acids (C_{18} : 1 – C_{22} : 1)	$HOOC(CH_2)_nCH{=}CH(CH_2)_mCOOH$	2.8 – 25.4
ω-Hydroxyalkanoic acids (C_{16} – C_{26})	$HOCH_2(CH_2)_nCOOH$	10.8 – 33.0
ω-Hydroxyalkenoic acids (C_{18} : 1 – C_{22} : 1)	$HOCH_2(CH_2)_nCH{=}CH(CH_2)_mCOOH$	11.4 – 25.7
C_{16} Functionality acids		
7,16-Dihydroxyhexadecanoic acid **8**	$HOCH_2(CH_2)_8CHOH(CH_2)_5COOH$	2.1 – 4.0

C_{18} Functionality acids		
Octadec-9-en-1,18-dioic acid **10** [*2027-47-6*]	$HOOC(CH_2)_7CH{=}CH(CH_2)_7COOH$	2.8 – 10.2
9,10-Epoxy-octadecane-1,18-dioic acid **11**	$HOOC(CH_2)_7HC\text{—}CH(CH_2)_7COOH$ (O)	4.0 – 15.9
9,10-Epoxy-18-hydroxy-octadecanoic acid **12** [*3233-92-9*]	$HOH_2C(CH_2)_7HC\text{—}CH(CH_2)_7COOH$ (O)	5.0 – 15.3
9,10,18-Trihydroxy-octadecanoic acid (phloionolic acid) **7** [*496-86-6*]	$HOCH_2(CH_2)_7CHOHCHOH(CH_2)_7COOH$	2.0 – 5.4
9,10-Dihydroxy-octadecanedioic acid (phloionic acid) **2**	$HOOC(CH_2)_7CHOHCHOH(CH_2)_7COOH$	2.0 – 8.8
Aromatic		
4-Hydroxy-3-methoxycinnamic acid (ferulic acid) **13** [*537-98-4*]	$HOC_6H_3(OCH_3)CH{=}CHCOOH$	7.0
3,5-Dimethoxy-4-hydroxycinnamic acid **14** (sinapinic acid) [*530-59-6*]	$HOC_6H_2(OCH_3)_2CH{=}CHCOOH$	
4-Hydroxy-2-methoxy-benzoic acid **15**	$4\text{-}(HO)C_6H_3 - 2\text{-}(OCH_3)COOH$	
4-Hydroxy-3-methoxybenzaldehyde (vanillin) **16** [*121-33-5*]	$4\text{-}(HO)C_6H_3 - 3\text{-}(OCH_3)CHO$	
Ferulic acid esterified with methyl fellonate **17**		

(**7**). The composition of suberin monomers is shown in Table 1 [14, 15, 19–27].

Several triterpenes and sterols constituents of waxes were also isolated from suberin [19].

The composition of the aromatic fraction of cork suberin is not completely elucidated. The structure of the phenolic part displays features similar to those of lignins. Alkali-depolymerized cork contains large amounts of phenolic compounds (ca. 60 %) [28]. Aromatic acids, not occuring in lignin, have been identified, such as 4-hydroxy-3-methoxycinnamic (ferulic) (**13**), 3,5-dimethoxy-4-hydroxycinnamic (sinapinic) (**14**), and 4-hydroxy-2-methoxybenzoic acids (**15**), together with 4-hydroxy-3-methoxybenzaldehyde (vanillin) (**16**), and esters of the ferulic acid esterified with fellonic (**17**) and other suberinic acid [14, 17, 29–31].

1.4.2. Lignin (→ Liginin)

Although several attempts have been made to extract and characterize cork lignin its structure has not been fully established. The nature of linkages between lignin and aromatic units of suberin is unclear. It is not possible to isolate a "Milled Wood Lignin" (MWL) by the extraction of ball-milled cork with aqueous dioxane at room temperature, applied for the isolation of lignin from wood [32], indicating that, if any "lignin-like polymers" occur in cork, they must be covalently bound to suberin [33], [46]. Furthermore, the calculation of 40 % "lignin" in cork from the methoxyl content (5.6 %) of whole cork [46], does not take into account the methoxy groups in hemicelluloses, e.g., 4-O-methyl-glucuronoxylan, as well as those in suberin itself, e.g., ferulic acid esterified with methyl fellonate (**17**, Table 1).

When ground, extracted reproduction cork was heated for 4 h at 160 °C with ethanol/water (1 : 1, v/v), an "Organosolv Cork Lignin-Like Polymer" (OCL) was obtained in just 2.6 % yield, that still contained "residual aliphatic moieties" [40].

In order to hydrolise the assumed ester bonds between lignin and suberin (Figure 4, see next page), ground reproduction cork was first treated with sodium methylate in methanol and the residual cork (34.4 %) then treated by the Björkman procedure, to yield 4.1 % "Saponified Milled Cork Lignin" ($MCL_{sap.}$), which, based on the results of analytical pyrolysis, was claimed to be similar to softwood MWL [42]. However, a comparison of $MCL_{sap.}$ with MWL from spruce wood by thioacidolysis revealed that $MCL_{sap.}$ contained 34 % less β-O-4 linkages and, by permanganate oxidation, gave 21 – 23 % less oxidation products than the spruce MWL [43].

As, β-O-4 linkages are indicative for the discrimination between lignin and bark polyphenols, taking into account the low yields of permanganate oxidation products as well as those of OCL and $MCL_{sap.}$, it may be well concluded that the aromatic moieties in cork, linked to suberin, are to be classified as bark polyphenols rather than lignins.

1.4.3. Polysaccharides

Cellulose represent ca. half of the total polysaccharides of cork (5 – 10 %). Hemicelluloses i.e., heteropolymers, which include several different sugar moieties (arabinose, xylose, glucose, galactose, etc.) constitute the other half [15].

Three types of hemicelluloses are found in cork: hemicellulose A and two hemicelluloses B (B-1 and B-2). Hemicellulose A contains xylose (95.2 %) and 4-*O*-methylglucuronic acid (5.9 %) [40]. Hemicellulose B-1 is composed of xylose, 4-*O*-methylglucuronic acid, arabinose, galactose, mannose, and glucose in the molar ratios 135 : 12 : 7 : 11 : 2 : 30 [41]. Hemicellulose B-2 is more highly branched than hemicelluloses A and B-1 and contains xylose, arabinose, glucose, galactose, 4-*O*-methylglucuronic acid, and rhamnose in the molar ratio of 17 : 12 : 12 : 6 : 4 : 1 [42]. The model of the hemicellulose structure from cork of *Quercus suber* L. is depicted in Figure 5 (see below Table 2 on pages after next) [43].

1.4.4. Waxes

The neutral compounds, extracted from cork by apolar solvent, include *n*-alkanes ($C_{16} - C_{34}$), fatty alcohols (with even numbers of C-atoms from $C_{18} - C_{26}$, containing traces of intermediate alcohols with an odd number of C-atoms and some unsaturated alcohols), glycerol, triglycerides, triterpenes of the friedelane and lupane families, and a very small fraction of monocarboxylic fatty acids (C_{16} and C_{24}). The triterpenes represent ca. 50 % of waxes and 2 – 5 % of cork [10,15,44].

The main components of the acid fraction are fatty acids, saturated even numbered C_{14} – C_{24}, odd C_{15}, C_{17}, C_{21}, and ω-hydroxyacids, triterpenes, sterols, and C_{20} and C_{24} alcohols. Table 2 (see pages after next) shows the chemical composition of the cork waxes, chemical and common names and structures [9,10,40–52].

1.4.5. Tannins

The tannins are phenolic and polyphenolic compounds which can be extracted from cork by polar solvents, such as water. The phenolic compounds may be monomeric (phenols, benzoic and cinnamic acids) and polymeric (hydrolyzable and condensed tannins). *Hydrolyzable tannins* are composed mainly of trihydroxybenzoic acid (gallic acid) (**56**) [*149-91-7*] or hexahydroxydifenic acid esterified with glucose (**57**). *Condensed tannins* originate from flavonoid type precursors by polycondensation reactions [44].

The phenolic compounds extractable from cork represent ca. 6 – 7 % of total cork corresponding to 95 – 98 % of tannins.

1.4.6. Other Components

The ash content of cork is ca. 1 – 3 %. Calcium is the most abundant inorganic constituent, in addition cork contains potassium, phosphorus and magnesium [1,53].

1.5. Physical and Mechanical Properties

Cork has a low density, which usually varies from 120 – 140 kg/m^3 depending on the region, the quality of the tree and the degree of humidity. Another special characteristic of cork is its great elasticity. When cork is rapidly compressed under elastic conditions it returns immediately to about 85 % of its initial volume and in 24 h about 95 % of its initial dimension are reached.

The average properties of cork are listed below [7]:

Figure 5. Model of hemicellulose structure of *Quercus suber*

Density	120 – 140 kg/m^3
Young's modulus	4 – 60 MN/m^3
Shear modulus	2 – 30 MN/m^2
Poisson ratio	0.15 – 0.22
Collapse strength (compression)	0.5 – 2.5 MN/m^2
Fracture strength (tension)	0.8 – 3.0 MN/m^2
Loss coefficient	0.1 – 0.3
Coefficient of friction	0.2 – 0.4
Thermal conductivity	0.025 – 0.028 J m K^{-1}

Because of its small Poisson coefficient (approx. 0) compression of cork parallel to the prism axis produces little lateral spreading [7], a property useful in gaskets. Cork is almost impermeable to gases and liquids, mainly due to the hydrophobic nature of the cell membranes. Cork sticks well to smooth surfaces even when humid, due to its elasticity, to the suction effect produced by the broken cells in contact with the walls and traces of resinous substances, aspects which are very important in a stopper. The friction coefficient $\mu_{\text{cork}--\text{glass}}$ is around 0.6.

Figure 6 shows a complete stress – strain curve for cork, depicting all the characteristics of a cellular solid. Cork is linear-elastic in the first stage, then its structure collapses and gives an almost horizontal plateau until the complete collapse of the cells causes the curve to rise steeply.

Figure 6. Stress – strain curve for cork

When a sharp object like a pin is stuck into cork, the deformation is highly localized. A layer of cork cells, occupying a thickness of about a quarter of the diameter of the indenter, collapses as it suffers a large strain. The indenter volume is absorbed by the collapse of the cells.

The presence of suberin renders the cork impermeable, and because of its content of tannins cork has no tendency to rot. A high concentration of oxygen is needed to incinerate cork and when the combustion starts (only at very high temperatures) cork burns on the surface and a layer of carbon forms and prevents the fire to spread. One can say it is a self-extinguishing material.

2. Cork Extraction

The first cork extraction (virgin cork) is done after the trunk of a cork oak has reached 0.7 m of perimeter [1].

Figure 7. Cork tree and cork extraction

The stripping when done well does not harm the trees because the first layer of reproduction cork merges with the continuously developing virgin layer in the unpeeled part of the tree. The "mother" (trunk surface after peeling) changes from a pink color to red ochre and afterwards to a reddish brown and finally to a gray crust-like formation [2].

After extraction, the reproduction cork is produced at a rate of 1.5 to 4 mm per year. In Portugal it is required by law to wait at least for 9 years after stripping before a new extraction in order to get a useful harvest (about 2 to 5 cm). This thickness is needed because it is related

with stopper diameter. In other locations a cycle of 12 years or even more may be needed. The collection of cork may be repeated every 9 years up to 12 or 15 harvests. Afterward, the tree will no longer be acceptably productive in general. Although yield varies greatly, an adult cork oak, with normal development, can produce from each stripping between 40 to 60 kg of cork [1], although much higher values (> 1 t per strip) can be achieved.

Harvest is between beginning of June and end of August. The cork is extracted in spring or summer because at this time the cork comes away easily from the trunk since the tree is growing and new cork cells are being generated. It is in the summer that the phelogen is in full production of new cork cells and it is easier to extract the bark by the disruption of these new-formed cells. The cut must be carefully done so as not to affect the mother layer. Care must be taken not to damage the cambium, which unlike the phellogen cannot regenerate itself. When wounded it heals very slowly and wood may start to rot. Even when this is avoided a scar will be seen in future cork and reduce its value. In the first harvest the good practice is not to cut higher than two times the perimeter of the tree at chest level and this height may increase in the following peelings up to three times this perimeter. A special axe is used for the harvest. The blade is used to make the incision while the end of the handle is shaped specially to detach the cork [1]. Besides this manual stripping also a mechanical process exists, based on small machines, that work using a blade with a sawing motion.

After the harvest "planks" are obtained that are dried in big-formed piles in the forest for approximately 3 – 6 months [1].

3. Production of Cork Based Products

3.1. Disks and Cork Stoppers

After harvest and stabilization cork is taken to the factory where the first operation of boiling takes place [1]. The major structural alteration due to boiling is the attenuation of the cork cells corrugation and an expansion of 10 – 15 % in the radial direction and 5 – 7 % in the other directions [54]. Boiling also decreases porosity by about 50 % [55] (see Fig. 8).

In boiling the cork is immersed in boiling water for approximately 1 h, usually in big open tanks with direct fire underneath. The aim of this operation is to remove dirt, insects, etc. to extract contaminating products and to render the planks softer and more flexible, and thus to facilitate the workability. The boiling water is regularly changed (at least every week) in modern systems.

After boiling to mature cork, it is left to ripen for two to four weeks in cellars (or some days after the new boiling process), sometimes under controlled hygrometric conditions. Very few thermophilic species of microflora, which eventually survived boiling and further recontamination, may appear on the planks. Finally, the edges are cut to make the planks rectangular, and the planks are inspected and selected according to thickness and quality (i.e., flexibility, homogeneity, color, evenness, and natural defects). 40 – 50 % of the original cork weight is lost in this step of cork preparation (separation of defects, drying, edge cutting) [1]. The best cork (about 25 %) goes to stopper production and the remainder is used for agglomerates.

The rectangular planks are cut into strips with a thickness corresponding to the diameter of the cork stopper and a width corresponding to the height of the stopper. The corks are punched with a cutting tube (rotating), the machines being more or less automated [1]. As lenticels lie parallel to the cell prism axis, cork cut parallel to this axis will leak. That is why natural cork stoppers are cut with the prism axis (and lenticels) perpendicular to the cork stopper axis [3,56]. After this, dimensional rectification, such as ends trimming and control of height and diameter, is performed.

The corks are classified in four to six categories, this selection being made by hand by specially qualified workers or by classifying machines (electronic optical reading). A good cork should be light and even in color, the pores being light and few in number. Harder corks may be chosen for wine under pressure [1].

The selection of cork stoppers is one of the most important operations in cork processing. Several parameters are analyzed, and a definition of cork defects for stoppers may be as follows [1]:

Figure 8. Effect of boiling on the cellular structure of cork

- Belly spots – surface depression caused by the dense inner surface of the cork strip;
- Chips – pieces missing from the cork surface (near the ends) due to dry or brittle cork material or faulty corker jaws;
- Cracks – fissures in the cork surface, which can cause chips;
- Dry year – narrow woody growth rings caused by lack of rain;
- Greenwood – undulation in the cork surface caused by moisture;
- Hardwood – hard rough areas on the cork surface caused by boring too close to the bark surface;
- Porosity – high-density pore activity;
- Worm holes – holes caused by worms.

To improve the appearance, the pores or lenticels can optionally be filled in with a mixture of cork powder and glue. Afterward the corks are washed (in tanks or automatic rotating machines), nowadays normally with a peroxide solution. After washing the corks are dried to 6–8 % moisture content. They can also be satin finished, i.e., covered by a fine film of paraffin (solid, oil emulsion) or silicone to facilitate cork stopper extraction and are marked (ink or fire) [1,56]. All the products used in finishing are of food grade.

Cork stoppers can be sold as finished or semi-finished products. In the first case marked and treated corks are packed in plastic bags under vacuum and SO_2. In the second case raffia or jute bags are usually used.

To produce *cork disks*, the thinnest good quality cork (not thick enough for cork stopper manufacturing) is used. From these planks the belly and the rasp are cut to obtain a clean slab of cork from which disks are cut and then dimensionally finished.

3.2. Granulates and Broken

Waste cork from the stopper industry, low quality cork (refuse), and possibly virgin cork are used to produce *cork granulates*. The granulates are separated and classified according to density and grain size. These cork granulates can be used as a final product in several applications or used as raw material for the production of composition cork. The finest are used to produce linoleum.

Broken is the name of small pieces of cork obtained from the breaking and first trituration of cork waste in order to reduce volume, e.g., for transportation.

3.3. Composition Cork

Composition cork is made of granules, which have been joined together using different synthetic or natural binding agents [1]. The agglutination is made, e.g., with asphalt, rubber, casein, cement, gypsum, plastics, urethane, melaminic, or phenolic resins [2]. Composition cork is usually produced in sheets, rolls, or blocks, or even extruded or molded.

3.3.1. Floor and Wall Coverings (→ Floor Coverings)

Floor and wall coverings made of cork are usually produced in the form of tiles, with different thickness, densities and finishing: simply polished, waxed, varnished or with a poly(vinyl chloride) layer. This last group may use a decorative sheet between the PVC and the agglomerate underneath [1]. A cork layer associated to a medium-density fiberboard (MDF) basis, for example, constitute a new type of flooring, known as floating floor coverings. The finest cork granules are used to produce linoleum [2].

Wall coverings have a density of 200–300 kg/m^3 and floor coverings of 400–500 kg/m^3. A mixture of cork granules and glue and/or other additives is filled into a mold which is then closed and heated usually at more than 120 °C for some hours to produce a block which upon cooling (or not) is then sliced into sheets, which are then dimensionally finished. These sheets can be painted, varnished, or covered with layers of other materials.

3.3.2. Agglomerated Disks and Cork Stoppers

For the production of agglomerated cork stoppers cork waste from the cutting stage (until 90 % of the granulated material) is used or material rejected at the stopper sorting stage. Contaminated material should be avoided.

There are simple agglomerated corks and two types of composite stoppers, the stopper for champagne and sparkling wine (head in agglomerate and two or more disks in the bottom) and the "1 + 1" stopper for the other wines (body in agglomerate and one disk in each end).

Champagne corks comprise an upper part of agglomerated cork made be molding, extrusion, or block cutting and usually two or three disks of natural cork, which are in contact with the wine. This special type of corks has thre distinct parts: the "head" that protrudes out of the bottle, the "wheel" which is the part in the neck of the bottle, and the "mirror" which is the part in contact with the wine [6].

3.3.3. Corkrubber

The production of corkrubber is similar to the production of rubber-like products. Rubber and cork granules are mixed in rolls and the mats obtained are introduced into a mold, which is heated for polymerization. The heating process may take from several hours (in a typical oven) to some minutes (in microwave systems).

The most common corkrubber materials include a portion of cork granulates (60–70 kg/m^3), ranging from 15–260 parts of cork per 100 parts of rubber in weight. The main types of rubbers used are styrene-butadiene, acrylonitrile-butadiene and acrylic rubbers.

3.4. Insulation Corkboard

Insulation corkboard (ICB) is a product made of granules of cork expanded (steambacked) in autoclaves ($>$ 300 °C, $\sim$ 50 kPa) and agglomerated by pressure and temperature without any exogenous glue. Heat expansion results in an increase in cell volume of about 100 % and so the granules are compressed against each other and in the junctions the cells collapse. The blocks formed are then cut into planks which are then finished as required [57,58]. The main characteristics of ICB are listed in Table 3 [57,59].

Table 3. ICB average characteristics

Characteristic	Value
Density	110 kg/m^3
Thermal conductivity coefficient	0.045 W m^{-1} K^{-1}
Specific heat	1.9 MJ kg^{-1} K^{-1}
Thermal expansion coefficient	40×10^{-6}
Limit of pressure∗	10 000 kN/m^2
Permeability	3×10^{-5} m^{-1} h^{-1} Pa^{-1}
Tensile strength	0.05 MPa
Compressive strength at 10 %	0.25 MPa
Bending tension∗∗	1.6 kN/cm^2

∗ limit of pressure under which the material has an elastic behavior
∗∗ force for bending a material with a cross surface

Although such an agglomerate is produced with the lowest quality types of cork it has very favorable properties for some applications. Insulation corkboard is used for three applications: thermal insulation, acoustical absorption, an vibration insulation. The first application is the most important one. Acoustical corkboard,

for acoustic insulation is fabricated from specially selected raw materials, using granules of smaller size, lower density, and careful fine finish [59]. For vibration insulation higher densities are used.

Agglomerate for insulation cork board is exclusively made from cork granules (mainly from winter virgin cork) of a larger size (usually 5 – 20 mm) than those used in composition cork.

3.5. Other Specific Products

Most other cork products are made by similar processes as used for floor and wall covering cork products. For example, *filler and expansion joints* are specially designed to neutralize the expansion and contraction phenomena that can jeopardize concrete constructions, being an excellent protection against cracks, usually due to temperature variations. These materials can withstand continuous strain, whatever the moisture conditions are.

4. Uses

4.1. Stoppers

Good wines are made to grow and mature and they have to be protected from the environment but have to establish with it a slow and subtle relationship of exchange that only the cellular structure of cork can ensure. The friction coefficient of cork is high providing the ability to adhere glass due to the elastic force and the microscopic suction pads (cut cells).

Agglomerated corks are most commonly used in sparkling wines, but also in a sizable percentage of table wine (fast consumption wine). These corks are of very uniform size and density but are unlikely to provide the aging capabilities of the traditional cork stopper [1]. Colmated corks (pores covered with a mixture of cork powder are glue) are attractive low cost stoppers but are used only in common table wines.

The type of surface treatment applied on the cork stopper is determined by the type of wine and corkage cadence. The recommended moisture content for the stoppers in corkage is 6 – 8 % and the corker machine must press only 1 – 1.5 mm below the entry bore, avoiding compressions of more of 1/3 of the stopper diameter. When filling, an empty space level should be respected. After corking the bottle must be maintained in a stand-up position for some minutes to allow the dimensional recovery of the cork stopper.

In champagne corks, the base, where sealing is most critical, is usually made of two disks cut with the lenticels crossing the disks' thickness. Leakage problem is avoided because the lenticels of two or more disks do not connect [6].

4.2. Civil Construction

In buildings and other civil construction works, cork products may be used for thermal insulation and insulation, acoustic correction, floor covering, wall covering, false ceilings, and expansion joints:

- Thermal insulation – ICB
- Vibration insulation – ICB, corkrubber
- Acoustic correction – ICB, composition cork
- Floor covering – composition cork, cork rubber
- Wall covering – soft composition cork
- Expansion joints – composition cork

Some of these cork products may be used as composites with other construction materials, for example, ICB with polyurethane, composition cork with MDF and wood veneer, or may be covered by waxes, varnishes, and paints.

4.3. Industrial Applications

Some specific applications of cork in the industry include: cork slabs and sheets, pipe insulation, battery mold coating, cold storage insulation, machinery anti-vibration sheets, and storage tank insulation.

As expanded cork agglomerate (ICB) maintains its properties at very low temperatures, it has a wide range of applications in the refrigeration industry. The electrical industry uses corkrubber to stop leaks of transformer fluids. Similar products are also used in the manufacture of electrical switches, lightning apparatus and the like [2]. The ceramic industry uses cork

disks to smooth edges and to eliminate defects [2].

High density expanded agglomerate planks are one of the best means of insulating machines and damping vibrations [2, 59].

4.4. Automotive Industry

Cork makes good gaskets because it accommodates large elastic distortion and volume change and its closed cells are impervious to water and oils. Almost all the gaskets used in automobiles are made of corkrubber since this combination is easy to cut and due to its flexibility and resistance it can be used in gaskets with very narrow borders [2, 7].

4.5. Other Specific Uses

Other specific uses include: baseballs, cricket, hockey, and golf balls, golf clubs, plate mats, memoboards, musical instruments, polishing blocks, radioactive isotope capsules, ashtrays, bath mats, beehives, candle holders, glass coasters, cork paper, insulation in solid fuel rocket motor cases, desk pads, cork textiles, fishing rods rings and handles, fishing net floats, handicraft items, hot pads, jar lids, buoys, safety helmets, shoes, shuttlecocks, table-tennis bats, whistles, bungs for gun cartridges, calendars, etc.

5. Quality and Standardization

5.1. Standardization and Testing

Cork standardization was initiated in Portugal in 1957 with the establishment of the Technical Committee (TC-16) aiming at the development of standards for cork and industrial cork products, from raw material and terminology to finished products. Currently about 40 standards exist. ISO/TC-87 working since 1958 has the same aim and is responsible for the production of international standards. Portugal has the Chairmanship and the Secretariat of this TC. Within CEN (Standardization European Committee) there are three TC whose scope is directly related to agglomerated cork applications: CEN/TC-88 (thermal insulation), CEN/TC-99 (wall coverings) and CEN/TC-134 (resilient floor coverings). Several European Standards are now published concerning test methods and product specifications, supporting harmonized standards to be converted at a national level [60].

For a list of European and international standards see [60].

The requirements and *methods of testing* for the different cork products, as well as these products classification are described in both national and international and/or European standards [60].

5.2. Quality in Cork Production

There are a large number of productive units, certified according to the EN ISO 9000 series standards. Furthermore, the recent adoption and implementation of the International Code for Cork Stopper Manufacturing Practice reinforces and adds credibility to the quality guarantee process. There are also accredited laboratories, which specifically perform specific tests for cork products.

The Cork Quality Council has instituted a common grading standard in order to eliminate differences in different companies to categorize cork stoppers (visual characteristics). This standard is designed to be used by buyers. The criteria allow classification of cork stoppers in four grades (A, B, C, and D). The visual grades are designed to describe a range of corks of similar appearance.

6. Economic Aspects

6.1. Forestall Production

The cork oak adapts to soils practically unable of supporting any other economically viable crops, and prevents the degradation of these soils. The value of this tree should not be measured merely by the cork produced but rather by the whole aspects of agriculture, forestry, grazing, hunting, etc.

Because of particular climatic conditions (temperature, light, and rainfall) the cork oak established itself in the Western Mediterranean

basin. It is found in Northern Africa (Morocco, Algeria, Tunisia), in Southern France (e.g., Corsica), Italy (Sardegna), Spain and, above all in Portugal. Worldwide cork oak forests cover an area of about 2.2×10^6 ha [1,61]. A breakdown of cork forest surface and cork production per year worldwide is given in Table 4.

Table 4. World cork wood surface and production per year

Country	Surface, ha	Production, t
Portugal	660 000 – 730 000 (28 – 35 %)	170 000 – 185 000 (54 – 63 %)
Algeria	410 000 – 480 000 (12 – 21 %)	15 000 – 27 000 (4 – 12 %)
Spain	410 000 – 500 000 (18 – 23 %)	80 000 – 89 000 (22 – 29 %)
Morocco	340 000 – 400 000 (9 – 18 %)	13 000 – 18 000 (4 – 7 %)
France	100 000 – 110 000 (1 – 5 %)	5000 – 32 000 (1 – 11 %)
Italy	90 000 – 100 000 (4 – 10 %)	20 000 – 26 000 (5 – 6 %)
Tunisia	90 000 – 100 000 (3 – 6 %)	8000 – 9000 (1 – 2 %)

The world average cork productivity is around 150 kg ha^{-1} a^{-1}. An average tree (in age and size) may provide up to 100 kg per strip, with 7 – 11 kg/m^2 of debarked area. However, in the best cases these values can be much higher [1]. Although prices can vary considerably, as a reference, the price of good quality cork for stoppers in Portugal, in the campaign of 2000, was around 3 – 3.5 €/kg.

The undergrowth in corkwoods is rich in a wide variety of aromatic and medicinal plants and is also home to game of significant economic value. Acorns are used for swine food, wood is used for small pieces but mainly for production of firewood and charcoal [61].

6.2. Personnel and Companies

At present more than 900 companies are operating in the cork business in Portugal , mainly in the north of the country (Santa Maria da Feira). These firm employ about 15 000 persons, 85 % of the factories have less than 20 workers. In Spain about 280 companies are active in this field, mainly in Cataluña (province of Girona), Extremadura and Andaluzia, 120 of these companies produce cork stoppers.

In Portugal about 6000 workers work seasonably in cork extraction and this figure allows an extrapolation for other countries. It is estimated that there are about 150 000 people around the world, which are dependent on the cork sector, including production, processing, and marketing.

6.3. Consumption of Products and Markets

Taking the Portuguese industry as reference, the breakdown of cork consumption according to product is as follows [61]:

Natural cork stoppers	57 %
Agglomerated cork stoppers	11 %
Composition cork board	17 %
Insulation cork board	6 %
Other	8 %
Non finished products	1 %

As a reference (for the year 2000) a first quality cork stopper can cost as much as € 0.35 but a very wide range of prices exists for all types of cork stoppers, starting at less than € 0.05.

One square meter of simple cork floor covering can have a price as low as € 7 – 8, but also here a wide range is found.

Annual world consumption of cork products is given below [2]:

Cork stoppers for wine	13×10^9
Stoppers for champagne and sparkling wine	1.5×10^9
Insulation cork board	150 000 m^3
Floor tiles	10×10^6 m^2

The importance of the main sectors of cork products utilization, taking the Portuguese production as a reference, is as follows [4]:

Wine sector	61 %
Automobile sector	11 %
Civil construction	15 %
Other	13 %

6.4. Producers

Currently the cork industry is spread over different areas of activity:

– The preparer branch: selection and preparation of cork for the manufacturing industry

– The manufacturer branch: production of items by simply cutting the cork planks
– The crusher branch: production of cork granulates and raw materials for the cork board industry
– The blender branch: production of different types of cork boards

Cork products are manufactured both in small family companies and very large companies with thousands of employees. Some of the companies produce only one type of cork products, for example stoppers, and others manufacturing the entire variety of cork products.

Portugal and Spain process around 75 % of the world's cork production; France, Italy, and the North African countries produce together around 10 %, the remaining 15 % is scattered over different countries in Eastern Europe, Japan, Switzerland, Germany, UK, Latin America, India, and USA [1].

The most important producer is the Portuguese Amorim Group, which started its business in 1870. This group has 34 factories in Portugal and other countries with a total of more than 4000 workers and total sales in 1999 of about € 512 million, accounting for about 1/5 of the world cork processing capacity. This group produces cork components for almost all kinds of applications.

The second largest cork producing country is Spain, with the company Corchos de Mérida that produces 200×10^6 of cork stoppers (natural and granulates) with a transaction volume of € 18 million.

7. Environmental and Toxicological Aspects

7.1. Industrial Wastes

Most of the waste materials produced in cork processing are used in other types of cork products and therefore cannot be considered as an industrial waste. However, the cork processing still gives rise to real specific waste materials such as cork dust, cork boiling wastewaters, stoppers washing waste solutions, and steambaking condensates.

Cork powder waste (cork dust) is formed in different industrial cork processing operations and from different cork types. Worldwide cork powder production is around 50 000 t/a [62]. For studies on cork dust composition see [63].

By definition, cork dust is the group of cork particles with a size smaller than 0.25 mm [62]. Cork dust and cork fungi (from cork processing and manipulation) may be present in the air, even if extraction systems are installed in the factories. Prolonged occupational contact with these agents, if care with protection systems such as masks is not taken, may be related with an illness called suberosis.

Considerable quantities of cork dust are produced in grinding, granules cleaning and separation, cutting, sanding, and other finishing operations. More than 25 % of processed cork becomes cork dust [62]. Pure cork dust may be used in cork stoppers finishing operations and other specific applications [68, 69]. The rest is incinerated to produce steam (e.g., for ICB backing) or energy (drying, electricity etc.). This waste has a high heating value (15 – 28 MJ/kg). For ICB production 180 kg of cork dust are consumed per cubic meter [1] or 1.45 kg per kilogram ICB [70].

Steambaking Condensates. The ICB steambaking condensates are dark brown substances, which consist mainly of tannins and waxes. The amount of steambaking condensates formed annually is difficult to estimate but according to some calculations is about 1000 t/a.

Wastewater. The wastewater from cork processing amounts to 0.45 m^3 per ton boiled cork [1] (120 – 130 t/a world wide, mostly tannins).

7.2. Recycling and Treatments

Cork materials formed as waste in one operation can often be used in another operation of cork transformation. For example, the waste of cork from the cork stopper industry is used to produce cork granulates and cork powder from different origins is used to fill pores of some stoppers or is used as an energy source in cork factories [62] (see Section 7.1).

Cork grinding waste can be used as a substrate for plants with very good results [71] in germination and plant growing.

Used cork stoppers may be used as a raw material for the production of cork granulates or for the production of utilitarian wares (e.g., cutlery holders, table wares, pullers) according to a patented process [67].

7.3. Emissions

In the production and processing of some cork based products sometimes adhesives, varnishes, paints, glues, coatings, and other additives are used. Substances are formed or liberated and are emitted from the plants and eventually from finished products.

When urea – formaldehyde or phenol – formaldehyde resins are used as adhesives for cork materials, the finished products can potentially emit formaldehyde. The emission depends on the type of binding agent, catalyst, operational conditions, stabilization periods etc. (see → Formaldehyde; → Phenolic Resins; → Amino Resins). Studies carried out on cork materials showed that the level of formaldehyde emitted from cork board ranged from about 0.02 to 0.2 mg/100 g, formaldehyde emitted by natural cork ranged from 0.03 – 0.04 mg/100 g. The stabilization period (after manufacturing and before marketing) has almost no effect on this [72].

8. Legal Aspects

Protection of acorn production date back as far as the Costumes de Castelo Rodrigo e Castelo Melhor in 1209 in Portugal [2]. Further legislation was enacted during the following centuries to protect the cork tree, setting regulations for thinning, pruning, and stripping the cork. Current legislation covers the fields of forestland, cork oak, cork, and the cork oak farmer. The cork oak is protected from the moment of germination. A special license is required to fell trees. The same law requires the tree owners to take preventive measures, regarding to diseases, fire and damages by animals. Thinning is only permitted if the normal density is disrupted and the owner must notify the authorities. Pruning is only permitted from December to March. The tree may only be stripped for the first time when the trunk has a perimeter of 70 cm and extraction of reproduction cork is expressly prohibited if this cork is less than 9 years old [1, 2].

1. Introduction

The conventional or "one-at-a-time" approach for discovery and process or performance optimization in the areas of biopharmaceuticals, materials science, and catalysis has traditionally been a time-consuming and expensive endeavor and often relies upon a large number of iterative steps. This is because technological problems are largely multivariable in nature and it is seldom possible to predict a priori which of the variables are most important in arriving at a solution. Increasing competition in the chemical and pharmaceutical industries has necessitated faster and more efficient means of identifying new materials and formulations. This drive towards increased research productivity was first encountered in the pharmaceutical industry, where long development times and high research costs resulted in the introduction of new R & D approaches designed to accelerate the drug-discovery process. One such approach is the use of high-throughput methods for rapidly synthesizing and screening large numbers of potential drug candidates for their biological activity. Most major drug manufacturers now utilize this so-called combinatorial chemistry (→ Combinatorial Chemistry) as an integral part of their research and development programs [1–8].

In the broadest terms, the combinatorial approach involves the design and high-throughput synthesis and screening of arrays containing large numbers of chemical or biochemical materials or formulations. Arrays (often referred to as libraries) are designed to span a particular variable or phase space of interest and are screened for one or more physical properties or chemical parameters of interest. The term "high-throughput" can be somewhat subjective, and generally depends upon the particulars of the chemical problem under study and rates of conventional experimental throughput. For example, in pharmaceutical research high-throughput can refer to the synthesis and screening of hundreds of thousands of drug candidates per year. In other areas this number may be higher or considerably lower but still well beyond the capabilities of conventional research.

The combinatorial approach has found application not only to the discovery and optimization of new materials or formulations but also existing (and possibly commercialized) ones as well. The path towards discovery, optimization, and eventual commercialization of such materials or formulations is depicted in Figure 1. The combinatorial approach begins with high-throughput screening, which can be divided into various stages. During the first stage, referred to as primary screening, many experimental combinations are surveyed as quickly as possible for one or more properties or performance characteristics to eliminate the vast majority of combinations. The figures of merit chosen to analyze each combination may be measured directly or by inference from another related property. To accommodate the high-throughput of a primary screen it is often necessary to tolerate certain compromises in the quality or precision of the data obtained. Materials or formulations that meet certain performance criteria during the stage of primary screening (hits) are then investigated more thoroughly in a secondary screen. Typically, secondary screening involves preparation of libraries of materials or formulations on a larger scale under more controlled conditions, and an analysis that is more rigorous and discriminating. As a result, the number of experiments performed in the secondary screen is typically smaller than in primary screening, the trade-off being throughput versus precision of data. Candidates that perform well in secondary screening are then selected for further studies (tertiary screening), for example, to optimize performance or establish structure – activity relationships. In this stage of the screening process, arrays are constructed by using phase space parameterized around key experimental variables identified during secondary screening. The process is iterated until materials or formulations with the desired properties or performance criteria are discovered.

Figure 1. Process of discovery and optimization of a commercial material or process by combinatorial methodologies

For example, a primary screen for a new catalyst system might be based solely upon activity. The most active elements of the libraries screened would then be chosen for secondary screening, in which catalyst activity and another property, such as selectivity, are determined. Those catalysts that have the best performance based on activity and selectivity in the secondary screen might then be singled out for further study using focus libraries to optimize catalyst performance. The focus libraries might include structural variations of the catalysts that emerged from the secondary screen or a more expansive range of experimental conditions than were initially used.

The materials emerging from the combinatorial process of primary, secondary, and higher order screening are then studied further by conventional methodologies employing standard laboratory reactors and characterization tools towards the goal of producing a new or improved commercial product (Figure 1). Exactly what stage conventional, one-at-a-time methods enter the process of discovery and optimization and what these methods entail depends largely upon the material or process being studied. Conversely, there may be practical limitations to the scope and applicability of combinatorial methods. For example, the implementation of a new catalyst discovered by combinatorial approaches may require conventional, one-reaction-at-a-time scale-up studies in batch reactors and pilot plants prior to implementation in a commercial process. In this example, combinatorial approaches are a powerful research tool used in advance of or in conjunction with more conventional methods of discovery and optimization.

The efficient execution of the combinatorial approach requires the use of rapid serial or parallel synthesis and analytical methods augmented by the judicial use of automation, miniaturization, and software and database technologies. Miniaturization and automation are often critical to accommodate the experimental scale and relieve the tedium imposed in the creation of highly dense libraries. The use of hardware and software is also important, not only to enable automation, but also as an aid in library design and analysis. Moreover, the accumulation of a tremendous amount of data related to the synthesis and screening of libraries must be efficiently managed. To this end numerous database and data-mining technologies such as bio- and chemoinformatics have been spawned [9]. The use of such data-managing technologies allows key and often nonobvious structure – function relationships to be understood, thereby providing a wealth of information for use in future experimental designs. Indeed, the ability to conduct experiments in a high-throughput fashion not only allows the scientist the freedom to explore well-constructed ideas but also engenders serendipity.

The development of combinatorial technology for the biopharmaceutical industry was initially leveraged by the availability of low-cost, high-performance computers, robotics, molecular modeling, and database software, as well as tools created for the clinical diagnostics, optics, and semiconductor industries. Similarly, the first application of the combinatorial approach to nonbiological systems was developed by using technology that has its origins in the semiconductor industry. Seminal work by Schulz et al. in 1995 demonstrated the ability to prepare semiconductor materials in an array format and sparked tremendous interest in this field [10]. However, certain concepts related to the synthesis and characterization of arrays of materials can be traced back to work published by Hanack in the early 1970s [11]. Since then, combinatorial methodologies have been applied to the discovery of optical and electronic materials, magnets, polymers, and catalysts for commodity, specialty, and fine-chemical synthesis. This has been made possible through the application and adaptation of technologies first established in the pharmaceutical and materials science industries. For example, research in combinatorial

catalysis has taken advantage of numerous solid- and solution-phase synthetic methodologies that have their origin in the pharmaceutical industry [12–15].

An increasing number of reviews address new methods in combinatorial chemistry and high-throughput synthesis and screening for chemical process development [16] and catalysis [17–22], and a glossary of frequently used terms has been published [23].

2. Enzyme Mimetics and Metal Complexes as Enzyme Mimetics

Enzymes have found widespread use in industry in a multitude of chemical reactions because of their excellent selectivities and high activities under relatively mild reaction conditions [24]. An ongoing field in research is the rational design and synthesis of numerous classes of low and high molecular mass synthetic enzyme catalysts (synzymes) that mimic, improve, substitute, or exceed a natural enzymatic function or structure.

2.1. Combinatorial Libraries of Catalysts as Enzyme Mimetics

One approach to identify enzyme-like new organic catalysts is by searching through a multitude of "randomly" generated polymeric systems [25]. One of the first applications of this concept in combinatorial catalysis was the development of phosphatase-like catalysts [26, 27] and a combinatorially developed polymeric reducing agent [28]. Another example is the dehydration of β-hydroxyketones [29]. A library of 1344 polymeric variants with an amide functionalization ranging up to 20 % was obtained by aminolysis of poly(acrylic anhydride) and sets of mixtures of three to four amines taken from a library of 11 amines (Figure 2).

Assuming that these polymeric catalysts possess both acid and basic functional groups in proper spatial orientation for catalyzing the dehydration of β-hydroxy ketones, the researchers spectroscopically monitored the appearance of the β-aryl α,β-unsaturated carbonyl chromophore of the product. About 1 of the polymeric catalysts revealed a significant rate enhancement ($k_{cat}/k_{uncat} = 920$).

Figure 2. Example of a combinatorially functionalized polymeric catalyst based on poly(acrylic anhydride) facilitating the dehydration of β-hydroxyketones

2.2. Combinatorial Synthesis Enzyme Mimetics

2.2.1. Hydrolytically Active Metal Complexes

Enzyme mimics for activated ester or phosphate hydrolysis remain in the center of interest. Janda et al. synthesized and screened transition metal complexes as enzyme mimics that catalyze the hydrolysis of carboxylic esters [30]. The researchers extended their methodology towards the synthesis of the corresponding azacrown ether lanthanide complexes that were capable of hydrolyzing phosphate esters, a crucial chemical transformation in areas such as nucleic acid chemistry [31].

Using a split – pool approach (→ Combinatorial Chemistry), Berkessel and Hérault synthesized a 625-member library of undecapeptides on a solid support, which was assayed for catalytic activity in phosphate hydrolysis [32]. About 2500 beads were incubated with Cu^{II}, Zn^{II}, Fe^{III}, Co^{III}, Eu^{III}, Ce^{IV}, and Zr^{IV} solutions; only in the presence of Zr^{IV} catalytic hydrolysis activity was observed. [32]

2.2.2. Evolutionary Solid-Phase Synthesis of Oxygenase Mimics

The catalytic oxygen transfer activity of the enzyme Cytochrome P450 oxygenase inspired

Sames et al. to develop polymer-supported diamide complexes of manganese for catalytic oxygenation reactions [33]. Upon transformation into the corresponding manganese(III) complexes, the resulting catalysts were directly screened on-bead for the epoxidation of vinylbiphenyl (Figure 3). The first-generation library quickly showed that a number of structural variants led to respectable yields of the epoxide (74 % yield for the first-generation ligand). The second round identified a ligand which led to nearly complete consumption of vinylbiphenyl in 16 h (96 % yield). The third generation of ligands provided a cyclic system that exhibited the highest turnover rate of the entire assay; 5 mol % of this catalyst yielded 98 % of epoxide in 2 min, which translates into a rate enhancement by two orders of magnitude in comparison to the second-generation catalyst. The same catalysts were also used for the oxidation of ethylbenzene derivatives.

Figure 3. Evolution of diamide ligands for Mn^{III}-catalyzed oxygenation on a solid support

2.2.3. Libraries of Organic Acylation Catalysts

Mimics for acyl transferases require a concerted interplay between tethered functional groups, whereby the catalyst should possess a suitable base that is covalently tethered in close proximity and in the correct orientation relative to a nucleophilic center. Taylor, Morken et al. reported the preparation of a library of 3150 distinct nucleophilic acylation catalysts on approximately 7000 encoded polymer beads prepared by split – pool methods [34]. Temperature changes due to the exothermic catalytic acetylation of ethanol were monitored directly on the floating beads by IR thermography. The "hottest" 23 beads were then manually selected, and decoding revealed three novel structures as effective catalysts.

3. Combinatorial Catalysis in Asymmetric Synthesis

The importance and practicality of asymmetric synthesis as a tool for obtaining optically pure or enantiomerically enriched compounds have been fully acknowledged by chemists in the areas of synthetic organic, medicinal, agricultural, and natural products chemistry and their related industries [35]. Among asymmetric transformations, the most desirable and also the most challenging is catalytic asymmetric synthesis, in which one chiral catalyst molecule can create millions of targeted chiral product molecules in a process that has been termed "chirality multiplication". Thus, asymmetric catalysis has a significant economic advantage over stoichiometric asymmetric synthesis, and consequently the development of new methods for discovering asymmetric catalytic transformations is an important and emerging objective in chemistry. Among other approaches, divergent ligand synthesis strategies, in which an advanced ligand intermediate is transformed into a series of different chiral ligands, appear to be especially fruitful in this area. In most cases, the ligand bears the chiral information and therefore creates a discriminating chiral environment in close proximity to the active metal site of the catalyst. Asymmetric synthesis is an especially suitable area for

combinatorial catalyst discovery, since asymmetric catalysis is often mechanistically very complex, and critical variables in the parameter space to be evaluated for catalyst development and optimization are mutually dependent. Thus, by rapid parallel synthesis and metal complexation of chiral ligand libraries, coupled to automated or high-throughput screening, multidimensional problems in the discovery and optimization of catalysts may be efficiently addressed.

3.1. Combinatorial Catalyst Libraries in Enantioselective Additions of Dialkylzinc Reagents

The enantioselective addition of dialkylzinc reagents to aldehydes can be catalyzed by enantiopure aminoalcohols [36]. Ellman et al. reported the parallel solid-phase synthesis of a small library of chiral aminoalcohols, substituted 2-pyrrolidinemethanol ligands [37]. To anchor *trans*-4-hydroxy-L-proline methyl ester as a ligand scaffold to Merrifield resin, a parallel solid-phase synthesis approach involving a cleavable tetrahydropyranol linker was used. Subsequent nucleophilic addition of various Grignard reagents, followed by reductive *N*-alkylations, gave the desired aminoalcohols (Figure 4). On-bead screening of the asymmetric addition of diethylzinc to a variety of aromatic (up to 94 % *ee*) and aliphatic aldehydes (up to 85 % *ee*) yielded slightly inferior enantioselectivity compared to that of the corresponding free ligand in solution (Figure 4).

Gennari et al. used polymer-bound reagents [38], solid-phase extraction (SPE) [39], and polymeric scavengers [40] to speed up the synthesis of a library of 60 chiral Schiff base ligands that contain a set of different metal-binding sites (a phenol, an imine, and a secondary sulfonamine) [41]. Through a high-throughput screening approach, a ligand was identified that catalyzed the copper-mediated, enatioselective conjugate addition of diethylzinc to cyclic enones with up to 90 % *ee* (Figure 5).

In a related approach, Liskamp et al. developed a solid-phase synthesis of bis-sulfonamide ligands [42]. A library of these ligands was screened in a simultaneous substrate-screening

Figure 4. Parallel solid-phase synthesis of pyrrolidine-type catalysts and their screening in the enantioselective addition of diethylzinc to aldehydes

Figure 5. Ligands for enantioselective addition of diethylzinc, generated from combinatorial solid-phase synthesis

procedure for the ability to enantioselectively catalyze the $Ti(OiPr)_4$-mediated addition of di-

ethylzinc to aldehydes. The best solid-phase candidate was resynthesized in solution and gave enatioselectivities of up to 66 % (Figure 5).

3.2. Ligands for the Lewis Acid-Catalyzed Asymmetric Aza Diels – Alder Reaction

The asymmetric aza Diels – Alder reaction provides an effective route to optically active nitrogen-containing heterocycles [43]. Asymmetric catalysis of imine dienophiles has remained elusive, and successful asymmetric induction in the aza Diels – Alder reaction heavily relied on auxiliary-based methodology.

Kobayashi et al. reported a novel class of chiral zirconocene complexes that catalyze the aza Diels – Alder reaction of aldimines with Danishefsky's diene to afford the corresponding piperidine derivatives in high yields with high enantioselectivities [44]. In a solid-phase approach, polymer-supported (*R*)-1,1′-binaphthols (BINOLs) were synthesized and rapid catalyst optimization could be achieved (Figure 6). After synthesizing the most promising ligands in solution and further optimization of the inorganic precursor, a Zr complex was finally identified as the best catalyst, giving 68 % yield and 94 % *ee*.

Figure 6. Solid-phase approach for the identification of a catalyst for the asymmetric aza Diels – Alder reaction

3.3. Divergent Ligand Synthesis for Enantioselective Alkylations

In 1998, Burgess et al. highlighted in several examples the value of divergent ligand synthesis strategies for the preparation of focused ligand libraries and the use of ligand screening [45]. By definition, in divergent syntheses of chiral ligands, an optically pure material is produced and then subsequently used to prepare a class of structurally similar ligands.

Based on L-serine, a chiral building block (chiral synthon = chiron) was prepared as a key intermediate that was then converted into a family of 13 novel chiral phosphine oxazoline ligands using several different routes and employing conventional organic solution synthesis [45]. It was shown that the divergent ligand synthesis approach was very suitable for efficiently accessing this ligand class with good diversity in terms of steric bulk and/or electronic pertubation (Figure 7).

The ability of these ligands to asymmetrically catalyze the addition of dimethyl malonate to 1,3-diphenylprop-2-enyl acetate was investigated [46]. The best of these ligands gave a palladium complex that catalyzes the allylic alkylation with up to 94 % *ee*.

In a different modular approach to generate chiral catalysts for the same transformation, Gilbertson et al. synthesized a phosphine oxazoline ligand library from amino acids and phosphino carboxylate building blocks [47, 48]. The best of these ligands gave a palladium complex that catalyzes the addition of dimethyl malonate

Figure 7. Divergent approach to phosphine oxazoline ligands
Boc = *tert*-butyloxycarbonyl, R = alkyl, aryl

to 1,3-diphenylprop-2-enyl acetate in 99 % yield and with 98 % enantiomeric excess.

Kobayashi et al. developed a solid-phase strategy to synthesize novel chiral pentamine ligands for the α-alkylation of lithium amide enolates, and obtained enantioselectivities of up to 84 % [49].

3.4. Chiral Phosphine Ligands for Asymmetric Hydrogenation

In homogeneous catalysis, phosphines are a particularly important ligands in late transition metal catalyzed processes such as hydrosilylation, hydroformylation, carbonylation, olefin dimerization, and hydrogenation [50]. For example, industrially important hydrogenations are involved in the synthesis of *l*-dopa (Monsanto) and Merck's novel HIV protease inhibitor Indinavir marketed currently as Crixivan [51].

Figure 8. Screening of a library of support-bound α-helical peptide/phosphine Rh^I catalysts in enantioselective hydrogenation reactions of prochiral methyl-2-acetamidoacrylate to *N*-acetylalanine methyl ester

Gilbertson et al. synthesized a 63-member library of phosphine-containing amino acid ligands for the Rh^I-catalyzed hydrogenation of methyl 2-acetamidoacrylate to the corresponding amino acid derivative *N*-acetylalanine. Structurally unique chiral tetra- or pentapeptides were synthesized by combining the novel amino acids dicyclohexyl- and diphenylphosphine serine (Cps and Pps, respectively) with two or three hydrophobic amino acids, giving access to ligands that were used for the catalytic asymmetric hydrogenation (Figure 8, see above). Enantiomeric excesses of up to 38 % were obtained [52].

3.5. Asymmetric Reactions Catalyzed by Schiff Base-Type Ligands: the Positional Scanning Approach

A modular approach based on well-established functional building blocks can be used for the rapid discovery of novel catalysts [53,54]. The philosophy of this positional scanning approach for identifying a chiral catalyst consisting of three modular subunits, for example, is to optimize each of the three modular subuntits while keeping the other two constant. Common to the positional scanning approach (iterative optimization approach) of the modules comprising the ligand structure are the two assumptions (1) of an independent and additive influence of each of the building blocks, and (2) of the absence of negative cooperative effects during their systematic variation. In addition, the positional scanning approach, especially when coupled with automated screening, not only offers unique opportunities for the identification of substrate-specific catalysts (fine tuning) but also permits the discovery of ligands that possess unusual properties and which might otherwise elude detection.

In 1996, Snapper and Hoyveda reported the diastereo- and enantioselective addition of trimethylsilyl cyanide (TMSCN) to epoxides catalyzed by titanium Schiff base complexes to yield chiral β-cyanohydrins [53]. Chiral dipeptidic hemisalen ligands of the general structure SB-AA_2-AA_1-GlyOMe (SB = Schiff base or hemisalen, AA_i = amino acid) were synthesized in a modular fashion from various amino acid and aldehyde building blocks by using parallel solid-phase synthesis techniques. After cleavage from the solid support, complexation with a titanium alkoxide precursor, and parallel screening of the chiral Lewis acids for efficiency

and enantioselectivity, a potent catalytic system for ring opening of cyclohexene oxide with 89 % enantiomeric excess was discovered (Figure 9).

Figure 9. Discovery of a new Schiff base catalyst for the Ti-catalyzed enantioselective addition of trimethylsilyl cyanide (TMSCN) to *meso*-epoxides by an iterative optimization approach using positional scanning

Subsequent work by the same group demonstrated that screening did not require cleaving the Schiff base ligand from the solid support, which significantly accelerated the optimization process [55].

The positional scanning approach was used to identify novel catalytic systems for the asymmetric hydrocyanation of imines (Strecker reaction) [54], for enantioselective additions of cyanide to imines [56, 57], for Cu-catalyzed conjugate addition of alkylzinc reagents to cyclic enones [58], for Zr-catalyzed addition of diethylzinc to imines [59], and for Cu-catalyzed allylic substitutions [60].

3.6. Identification of Novel Catalysts for Asymmetric Epoxidations by the Positional Scanning Approach

In 1999 Jacobsen's group disclosed the discovery of novel chiral catalyst for the epoxidation of *trans*-β-methylstyrene (TBMS) [61] Out of 5760 possible metal – ligand combinations, a catalytic system comprising a chiral ligand and $FeCl_2$ was identified that produced moderate enantioselectivities (15 – 20 % *ee*) for the target reaction.

Yamamoto et al. describe the vanadium-catalyzed asymmetric epoxidation of allylic alcohols using α-amino acid-based hydroxamic acid ligands [62] To optimize the ligands, again the iterative positional optimization approach was used. The asymmetric epoxidations were performed in the presence of 1 mol % of $[VO(OiPr)_3]$ and 1.5 mol % of the best ligand, giving the corresponding chiral epoxy alcohols in 58 – 99 % yield and 76 – 96 % *ee*.

4. Multidimensional Combinatorial Screening for the Identification of Novel Catalysts

Conventional research in a "one-at-a-time" or serial fashion provides thorough quality control of the samples entering the screening process to insure that accurate data are obtained. Combinatorial methods that involve, for example, split – pool synthesis [23] are much faster and make the preparation of relatively large numbers of compounds feasible but often lack control over the purity of the compounds entering the assay screen. To combine the two extremes outlined above, methods have been developed that are based on parallel or array syntheses or screening in a spatially addressable format, usually with one compound per well, coupled to automated screens. This approach facilitates a relative high level of quality control and a significantly enhanced throughput relative to sequential methods. Thus, multidimensional problems in the discovery and in the optimization of catalysts can be efficiently addressed by coupling parallel ligand synthesis with automated or high-throughput multidimensional screens (e.g., metal precursors, ligands, solvents, and reactant ratios). An integrated instrumental set-up for parallel high-throughput catalyst screening should encourage researchers to investigate a broader variety of systems, some of which may be regarded as too unusual to warrant testing in a sequential fashion.

4.1. Catalyst Discovery and Optimization Using Catalyst Arrays

Intramolecular C–H insertion of metal carbenes generated by catalytic decomposition of diazocarbonyl compounds is a facile methodology for carbon – carbon bond formation. Burgess et al. used a highly parallel screening approach for the optimization of ligand – metal – solvent combinations for this reaction (Figure 10) [63]. Using the optimized set of reaction conditions ($AgSbF_6$, THF, 25 °C, 24 h), the desired product was obtained in 75 % yield and in a diastereomeric ratio of 3.5:1.

Figure 10. Discovery and optimization of a new catalyst for the intramolecular C–H insertion reaction of Rh carbenes from α-diazo esters for the synthesis of indolyl derivatives by high-throughput catalyst screening
L-Menth: L-menthyl; *dr* = diastereomeric ratio, DDQ = 2,3-dichloro-5,6-dicyano-1,4-benzoquinone

Using a small library of a novel phosphine oxazoline ligand class obtained by a divergent ligand synthesis approach [45, 64], parallel assaying was employed to evaluate and optimize the application of these ligands by Burgess et al. The ligands were screened simultaneously in a custom parallel reaction block with a 27- or 34-well format. The asymmetric alkylation of 1,3-diphenylpropenyl acetate with malonate was chosen as a classical test reaction (Figure 11) [46] Allylic alkylation with an enantiomeric excess as high as 94 % was observed.

The same concept was used to identify stereoselective catalysts for the diastereoselective reductive aldol reaction [65], for metal-catalyzed addition of amines to C–C double bonds [66], for Lewis acid catalyzed aza Diels – Alder reactions [67], for hydrosilylations [68], and for the metal-catalyzed reaction of enamines with Michael acceptors [69].

Figure 11. High-throughput screening of phosphine oxazoline ligands in Pd-catalyzed asymmetric allylic alkylation reactions

Figure 12. High-throughput screening of the Raney nickel catalyzed reductive amination between ketoester and the dipeptide Ala-Pro for Elanapril synthesis

Huffman and Reider from Merck Research Laboratories reported the discovery of improved conditions for the diastereoselective reductive amination in the large-scale synthesis of the ACE inhibitor Elanapril [70]. A multidimen-

sional screening approach was used to assay the effects of various heterogenous catalyst formulations and a variety of additives (Figure 12).

It was found that acetic acid and potassium fluoride as additives improved the (*S*,*S*,*S*) : (*R*,*S*,*S*) selectivity with Raney nickel in ethanol from 11:1 to 17:1. Simultaneously varying multiple reaction parameters reportedly led to increased diastereoselectivity and isolated yield improvement [90 %, (*S*,*S*,*S*) + (*R*,*S*,*S*) isomers].

4.2. Parallel Array Screening for Catalyst Optimization Using Discovery and Focused Ligand Libraries

In analogy to the pharmacological model of drug discovery, a large parent set of ligands can be screened for lead compounds. After screening of the ligand library and discovering successful hits, smaller, more focused daughter libraries can be created based on ligand structure – activity relationships, which result in a higher hit rate because of the closer diversity space. This screening approach is useful for the optimization of reaction parameters, especially when essential reaction parameters of the targeted reaction such as preferred ligand class, mechanism of the catalytic cycle, or metal precursor are already known.

Parallel solution-phase synthesis techniques and parallel-array assaying facilitated the identification and optimization of new chiral dirhodium(II) carboxylates for enantiselective Si–H insertion reaction of diazoesters with silanes [71]. A systematic search through the Available Chemical Directory (ACD) resulted in a set of 2000 useful alternative chiral carboxylic acid ligands which were divided into 80 different structural clusters [72]. Representative chiral carboxylic acid ligands from each of the 80 clusters were then used to prepare dirhodium(II) carboxylate catalysts. The first generation screen revealed α-hydroxy carboxylic acids and *N*-arenesulfonyl α-amino acids as promising ligand candidates. Based on these results, a focused second-generation array was constructed from the original 80 clusters to identify *N*-arenesulfonyl α-amino acids as superior ligands for the targeted reactions. Up to 76 % enantiomeric excess for the product was obtained with *N*-(toluene-4-sulfonyl)-L-leucine as ligand at − 78 °C (Figure 13).

Figure 13. High-throughput screening of rhodium insertion catalysts for the carbenoid insertion of azo esters into Si–H bonds

In a related approach, pyridine-containing ligands could be indentified that, in the presence of copper, catalyze the Ullmann aryl ether reaction [73].

5. One-Pot, Multi-Substrate Screening

Hadamard transformation is a mathematical algorithm that can be used to identify the property of a particular candidate of a group by recording the sum or superpositions of signals from well-selected groups or pools of single wells, catalysts, etc. [74]. Subsequent deconvolution of a data set obtained from an entire group coupled with computer simulations can provide analytical solutions in various branches of physical sciences, including homogeneous and heterogeneous catalysis. Many applications and scenarios of Hadamard transformations in combinatorial catalysis can be envisioned including multisubstrate/one-catalyst screening, one-substrate/multicatalyst (multiple ligands, metals) screening, or simultaneous screening of a variety of catalysts against multiple substrates.

Consequently, Kagan et al. investigated a Hamadard-type approach to combinatorial catalysis [75]. They examined the performance of one catalyst against multiple substrates in the asymmetric reduction of mixtures (families) of

prochiral aromatic ketones to their corresponding alcohols. Corey's chiral oxazaborolidine catalyst was chosen as the chiral catalyst (Figure 14).

Figure 14. One-pot, multisubstrate screening of a chiral oxazaborolidine catalyst in the enantioselective reduction of a family of aromatic ketones

Conversion and enantiomeric excesses of the resulting mixture of alcohols were monitored by conventional HPLC on a chiral stationary phase (CSP). The key was the careful calibration of the screening conditions, i.e., baseline separation of all of the ketones (starting materials), the corresponding alcohols (products), and the enantiomers of the product alcohols. In addition, all ketone reductions were repeated individually in solution. The maximal discrepancy between the individual asymmetric reductions and the multisubstrate approach ranged from 1 to 7 %. For example, asymmetric reduction of acetophenone resulted in the formation of (*R*)-1-phenylethanol with 97 % *ee* under screening conditions (ketone mixture) and in the reduction of the isolated ketone.

The one-catalyst/multisubstrate strategy was also used for the pooled synthesis of libraries of internal olefins by metathesis [76], for the enantioselective addition of diethylzinc to aliphatic and aromatic aldehydes [77], and for the resolution of racemates [78].

6. Combinatorial Approaches to Olefin Polymerization Catalysts

An annual production of around 46×10^6 t exemplifies the industrial importance of polyolefins [79]. New and versatile catalysts with improved performance represent highly desirable research goals. Productivity, molecular weight capability, temperature stability, comonomer incorporation capability, controlled comonomer sequence distributions, and the copolymerization of new monomer combinations are sought to be optimized. Recent studies have uncovered catalyst systems based on middle and late transition metals that show polymerization activites comparable to those reported for commercially employed single-site metallocenes [80–82]. Of particular importance was a diimine-based palladium catalyst, which was reported to copolymerize ethylene with previously incompatible monomers such as methyl acrylate. These discoveries have led to considerable interest in new nonmetallocene catalysts because of their high activity, ease of synthesis, and in particular, their tolerance of functionalized olefins [83–86].

Combinatorial approaches can be employed for both the discovery and optimization of new catalysts and new polymers. The discovery process typically involves the identification of new catalyst systems that may be employed for improvements to existing processes, or novel processes for new polymers. Upon identification of a new catalyst system, a high-throughput optimization procedure can be used to further improve catalyst performance through a detailed examination of the influence of ligand structure, activators, scavengers, solvents, and temperature.

Powers, Murphy et al. and Symyx Technologies developed a parallel synthesis and screening protocol for a polystyrene-bound 96-member library of 1,2-diimine nickel and palladium complexes (Figure 15) [87, 88].

The key intermediate, a polystyrene-bound 1,2-diketone was converted to a 48-membered 1,2-diimine library through a condensation reaction with 48 electronically and sterically diverse anilines. The ligand library was then divided and converted into 48 nickel and palladium complexes by reaction with [$NiBr_2$(dme)] and [PdClMe(cod)]. An analogous solution-based 1,2-diimine library was also synthesized in order to compare the performances of the polystyrene-bound catalysts with those of the corresponding solution-based catalysts. A custom designed 48-cell high-pressure parallel polymerization reactor (PPR) was used to screen the catalyst library for ethylene polymerization activity (Figure 16) [89].

Figure 15. Synthesis of Brookhart-type polymer-bound Ni^{II} or Pd^{II} 1,2-diimine complexes and their use in the polymerization of ethylene
M = Ni^{II}, X = Y = Br; M = Pd^{II}, X = Me, Y = Cl; R = alkyl, aryl, heteroaryl, halogen, functional groups; tag = chemical code; MAO = methylalumoxane, Ar_F = 3,5-$(F_3C)_2C_6H_3$; dme = dimethoxyethane; cod = 1,5-cyclooctadiene.

Figure 16. Parallel Polymerization Reactor-96 (PPR, Symyx Technologies)

Polymer products were assayed by a custom-designed rapid GPC technique [90]. The report also demonstrates the application of a chemical encoding strategy in which polystyrene-bound Ni^{II} and Pd^{II} complexes were encoded with cleavable tertiary amine tags. After a pooled polymerization, the tags were cleaved from the polymer products and detected by HPLC to reveal the identity of the catalyst.

The present work demonstrates the feasibility of applying solid-phase synthesis, on-bead screening, and encoding/decoding of pooled libraries of catalysts for the discovery and optimization of new olefin polymerization catalysts. More generally, Symyx has developed high-throughput methodologies for the synthesis and screening of supported and unsupported organometallic compounds for a range of important applications [91, 109].

Müllen et al. tagged silica- or polymer-supported heterogeneous catalysts for industrial olefin polymerization with a variety of fluorescent dyes [92]. Here, direct detection of the different product beads obtained by different catalysts is facilitated by fluorescent dyes that exhibit different emission wavelengths. The approach starts with producing the tagged catalysts by silica-supporting various metallocenes, activating them with MAO, and labeling them with different rylene dyes. The dyes were chosen because of their high chemical stability, their pronounced tendency to physisorb on silica, their high fluorescence yield, and because they do not influence the polymerization. These labeled catalysts were then mixed and introduced into a single polymerization vessel. During the olefin polymerization each catalyst par-

ticle forms only one product granulate through a particular growth process. To assign the different compounds of the product mixture to the employed catalyst, the polymer products are exposed to UV light, and can be directly identified, manually separated, and characterized, due to the different emission wavelengths of the labels. The feasibility of this concept was demonstrated for the polymerization of ethylene and for the copolymerization of ethylene and hexene.

Coates et al. used a pooled polymerization catalyst strategy to identify catalysts for the synthesis of syndiotactic polypropylene [93]. The basis of this concept is that the formed polymer itself serves as a stereochemical recording of the events on the polymerization catalyst. Assuming that the catalyst species do not react with one another, then a group of complexes for stereoselective polymerization can be screened simultaneously. When the desired polymer product has distinguishing chemical or physical properties, techniques such as solubility, spectroscopy, or chromatography can be used to quickly probe the crude product of a pooled polymerization reaction to see if a noteworthy catalyst is present. To probe this concept, a library of 12 salicylaldiminato ligands was synthesized separately by the condensation of three different salicylaldehydes and four amines (Figure 17). Equimolar amounts of these ligands were combined, deprotonated with BuLi, and treated with $TiCl_4$ to give a library of 78 possible titanium species. This complex library was then activated with MAO in toluene, and the resulting catalyst solution was exposed to propylene (ca. 0.3 MPa). Even though 90 % of the formed polymer could be washed away in refluxing diethyl ether (atactic polypropylene), the remaining 10 % of polymer was found to be syndiotactic polypropylene (^{13}C NMR microstructural analysis). Deconvolution methods, i.e., the synthesis and testing of sublibraries, were used to successfully identify the most active catalyst.

Chen et al. reported the use of electrospray ionization tandem mass spectometry (ESI-MS/MS) and gas-phase ion – molecule reactions for the rapid screening of Brookhart-type Pd^{II} olefin polymerization catalysts [94]. A test library of eight catalysts was prepared by treating eight diimine ligands with [PdClMe(cod)], washing and drying of the complex, and activation with AgOTf. The mixture was then dissolved in dichloromethane, saturated with ethylene, allowed to react for one hour and quenched with dimethyl sulfoxide (DMSO). After selection of ions with $m/z > 2200$ from the electrospray mass spectrum, these high-mass ions were collided with xenon to induce β-hydride elimination. From the corresponding daughter-ion spectrum the structure of the best catalyst can be derived.

Figure 17. Synthesis of a library of salicylaldiminato titanium complexes

7. Combinatorial Inorganic Catalysis

The application of combinatorial approaches to inorganic homogeneous and heterogeneous catalysis has received a great deal of attention recently. This is largely because of difficulties encountered in exploring implicitly vast areas of phase or variable space and the empirical nature of conventional work that typifies research in inorganic catalysis. To date, a wide variety of catalytic processes has been studied by the combinatorial approach, ranging from polyoxometalates in oxidation catalysis, oxidative dehydrogenation of alkanes, CO oxidation, and NO reduction, to areas such as electrocatalysis,

fuel cell research, and electrosynthesis. High-throughput synthesis methods based on thin-film deposition, solution deposition, and impregnation have been developed, as well as exciting new tools for high-throughput characterization.

7.1. Combinatorial Libraries of Homogeneous Polyoxometalate-Based Catalysts

Early transition metal oxygen cluster anions or polyoxometalates (POMs) have a significant impact in a variety of different research fields. Among catalysis by heteropolyacids, selective hetero- and homogeneous oxidation processes are of utmost importance [95].

Hill and Gall reported the combinatorial synthesis of phosphorous-centered molybdenum and tungsten polyoxometalates of the Keggin type [96]. The POM catalysts were evaluated in the selective aerobic oxidation of tetrahydrothiophene (THT) to its corresponding sulfoxide (THTO; Figure 18).

Figure 18. Aerobic oxidation of tetrahydrothiophene (THT) to tetrahydrothiophene sulfoxide (THTO) by combinatorially prepared POMs

The catalyst library was synthesized by combinatorially mixing stock solutions of appropriate tungsten, molydenum, and vanadium precursors at a constant phosphate concentration. Conventional gas chromatography was used to quantify product (THTO) yields and selectivities. Promising catalysts were selected and subsequently identified with the aid of ^{51}V NMR and IR spectroscopy, which revealed the complex $[\alpha\text{-}1,4\text{-}PV_2W_{10}O_{40}]^{5-}$ to be the most effective among them.

In a more recent contribution, Hill et al. reported a diversity-based discovery and mechanistic investigation of selective homogenous thioether oxidation by the $Au^{III}Cl_2NO_3/O_2$ system [97].

7.2. Combinatorial Libraries and High-Throughput Screening of Heterogenous Polyoxometalate Catalysts

Early efforts at Symyx Technologies led to the development of a fully integrated, high-throughput screening platform useful for pharmaceuticals and for fine-chemicals process discovery, screening, and optimization. The platform includes a proprietary software package for the design of combinatorial libraries. It also controls all the robotic functions, gathers data from each spatially addressable reaction entity, and automatically stores the process data in a central database. The hardware also comprises a variety of 96-well reactors equipped with a liquid- and slurry-handling robot. In one example, the integrated screening platform was employed for the high-throughput synthesis and screening of metal-doped polyoxometalate (POM) libraries in 96-well format [98]. Libraries of the heterogeneous POM catalysts were screened to discover selective aerobic oxidation catalyst systems. In this case, an imidazole alcohol was catalytically oxidized to the corresponding aldehyde, which represents an important key intermediate for the synthesis of DuPont's antihypertensive compound Losartan (Figure 19).

Figure 19. Application of high-throughput screening in the discovery of novel catalysts for the POM-catalyzed oxidation of imidazole alcohol to aldehyde, a key intermediate in the synthesis of the antihypertensive compound Losartan (DuPont Pharmaceuticals)

Within four weeks, 5000 experiments were performed to screen different catalyst compositions, effects of solvents, and additives under variable reaction conditions. Two classes

of catalyst systems that gave more than 90 % yield were identified. These results were confirmed and validated in subsequent scale-up experiments, but the proprietary catalyst composition was not disclosed.

8. Combinatorial Heterogeneous Catalysis

The mechanism of catalytic activity in a heterogeneous system is complex [99]. The distribution of active sites in heterogeneous catalysts and the phase integrity are in general poorly defined. The phase integrity plays a major role because the extent of deviation from the equilibrium structure under reaction conditions controls the catalytic function. These types of inherent problems severely hamper or even prevent the rational design of heterogeneous catalysts for a particular reaction. Conventional methods of catalyst discovery are primarily trial-and-error processes in which one catalyst is tested for activity at a time followed by numerous modifications to achieve satisfactory activity. The process therefore is time-consuming and laborious, and in most cases only local minima in a predefined parameter space (composition, reaction conditions, etc.) are identified rather than the absolute minimum. Combinatorial synthesis and screening offer a new dimension for the quick discovery and optimization of heterogeneous catalysts, both in terms of composition and process conditions. Integrated synthesis and screening of a plurality of catalysts in library format has been recognized as an essential factor [100]. For reviews on combinatorial heterogeneous catalysis, see [17, 19, 101, 102].

There are basically two techniques to prepare libraries of heterogeneous catalytic materials: solution-based methods and thin-film deposition methods (see Chap. 11). Impregnation of catalyst components onto a preformed solid support is an important solution-based technique for preparation of heterogeneous catalysts, but is seldom utilized for other materials science applications. The solution-based methods are predominant in the field of combinatorial heterogeneous catalysis. The majority of commercial heterogeneous catalysts are manufactured by solution-based techniques such as coprecipitation, impregnation, and variations thereof [103], and results from library experiments can thus be translated more easily into a bulk catalyst by using solution-based techniques. In addition, the solution-based methods present fewer scale-up problems. Furthermore, many liquid-handling robots and ink-jet-based liquid-dispensing systems can be employed to prepare heterogeneous catalyst libraries on a microgram to gram scale by solution-based methods. On the other hand, thin-film deposition methods are performed on custom-designed and -assembled high-vacuum instruments that generally require high initial investment. Special care should be taken to ascertain that the phase integrity of each catalyst member is the desired one, since the thin-film deposition methods rely on the interlayer diffusion for mixing, and the multicomponent layers occasionally result in phase separation. The thin-film method will perhaps be of choice for fused-catalyst libraries, e.g., metal alloys.

In most cases the catalyst performance depends on the method of preparation. Therefore, it is very important to adopt proper methods to obtain catalysts with expected surface area, uniform metal distribution, and desirable particle size. Newsam and Schüth have described various routes for combinatorial catalyst synthesis that include hydrothermal synthesis, use of fluid precursors, carrier impregnation, and precipitation [104]. Other methods of preparing combinatorial catalyst libraries include computer-controlled ink-jet deposition of liquid reactants [105], methods based on solution precursors [106–108], sol – gel techniques [109–111], impregnation of solid supports [112], and standard methods such as precipitation and coprecipitation [113, 114]. Table 1 summarizes some examples of heterogeneous catalyst libraries.

With the development of new and efficient technologies for the synthesis of large catalyst libraries, there is an ongoing effort for inventing fast and parallel screening tools for identifying active and selective catalysts. These techniques include resonance-enhanced multiphoton ionization (REMPI), time-resolved and differential IR thermography, scanning mass spectrometry, and colorimetry. While IR thermography and fluorescence or colored-dye assays are established techniques, a few new methods have emerged for identifying active catalysts in an array. So far, no screening method can offer a general solution to the problem of fast screening of

Table 1. Heterogeneous catalyst libraries

Catalyst libraries	Preparation method	Target reaction	Screening method	Ref.
0.5 % Ag, Bi, Co, Cr, Cu, Er, Fe, Gd, Ir, Ni, Pd, Pt, Rh, Ti, V, Zn, on Al_2O_3 pellets	solution-based impregnation	$H_2 + O_2$	IR thermography	[115]
37, 1 – 10 % Co, Cr, Cu, Fe, Ir, Mn, Ni, Pd, Pt, Rh, Ru, V, Zn on Si, Ti oxides	solution-based sol – gel method	hyrogenation of 1-hexyne	IR thermography	[116]
100 $Na_2O - Al_2O_3 - SiO_2$ zeolites with Li and Cs	solution-based hydrothermal zeolite synthesis	*	*	[117]
37 $TiO_2 - Al_2O_3 - SiO_2 - TiO_2 - ZrO_2$ zeolites	solution-based hydrothermal zeolite synthesis	*	*	[118]
645 clusters of Pt, Ru, Os, Ir on carbon	solution-based coprecipitation	methanol reforming	fluorescence acid – base indicator	[119]
120 ternary thin film clusters of Pt, Pd, Rh, and Pd, Rh, Cu	thin-film deposition: sputtering	CO oxidation, CO + NO	scanning quadrupole mass spectrometry	[120]
66 ternary combinations of 1 % Pt, Pd, and In on -Al_2O_3	solution-based impregnation	cyclohexane dehydrogenation to benzene	REMPI	[112]
16 Au/Co_3O_4 and Au/TiO_2 powders	solution-based coprecipitation	CO oxidation	quadrupole MS	[121]
33 1 – 6 % Ag, Au, Bi, Co, In, Cr, Cu, Fe, Mo, Ni, Re, Rh, Sb, Ta, Te, V, Y on Si, Ti, Zr oxides	solution-based sol – gel method	propylene oxidation	spatially resolved analysis of an array of batch microreactors	[122]
50 ternary and quaternary oxides of Co, Cd, Fe, Ga, Ge, In, Mn, Mo, Ni, Nb, V, W, Zn	solution-based coprecipitation	ethane and propane dehydrogenation	gas chromatography	[123]
30 binary combinations of Na_2WO_4 and Mn on SiO_2; Au and In on ZrO_2, TiO_2, SiO_2, MgO, ZnO, Nd_2O_3, Y_2O_3, CeO_2, Mn_2O_3	solution-based impregnation, deposition, and precipitation	oxidative coupling of methane and CO oxidation	quadrupole MS	[124]
66 ternary combinations of oxides of Mo, V, and Nb	solution-based sol – gel deposition	ethane oxidative dehydrogenation	scanning quadrupole MS, photothermal deflection, gas chromatography	[125]
144 ternary combinations of oxides of V – Al – Nb, and Cr – Al – Nb	solution-based sol-gel deposition	ethane oxidative dehydrogenation	scanning quadrupole MS, photothermal deflection	[126]
66 ternary combinations of 1 % Pt, Pd, and In on Al_2O_3	solution-based impregnation	cyclohexane dehydrogenation to benzene	quadrupole mass spectrometry	[127]
45 3 – 5 element combinations of Pt, Pd, Rh, Ru, Au, Cu, Ag, and Mn on TiO_2 and -Fe_2O_3	solution-based impregnation	C_3H_8 total oxidation	quadrupole mass spectrometry	[128]
56 quaternary combinations of Pt, Pd, In, Na on Al_2O_3	solution-based impregnation	NO reduction by C_3H_6	quadrupole mass spectrometry	[129]
$V_2O_5 - TiO_2$ mixtures	solution-based coprecipitation	oxidation on naphthalene to naphthoquinone	laser induced fluorescence imaging (LIFI)	[130]
36 Pt/Zr/V/Al_2O_3	solution-basedimpregnation	methane oxidation	scanning quadrupole MS coupled with monolith multi-channel reactor	[131]
52 Pt/Zr/V/Al_2O_3	solution-based impregnation onto Al_2O_3electrochemically formed on aluminum plate	methane oxidation	scanning quadrupole MS coupled with 35 parallel microreactors	[131]
715 combinations of Pt, Ru, Os, Ir, Rh	solution-based deposition	O_2 reductionH$_2$O oxidation	fluorescence acid – base indicator	[132]
280 V_2O_5, MoO_3, MnO_2, Fe_2O_3, Ga_2O_3, La_2O_3, B_2O_3, MgO on Al_2O_3	solution-basedimpregnation	propane dehydrogenation	quadrupole MS	[133]

* These publications only describe the synthesis of the libraries.

libraries together with the complexity involved in parallel detection of the reactants, products, and side products. Therefore, it is important to develop screening technologies according to the detection requirements of the reactants, products, and side products of the reaction. Accordingly, in some cases, it is essential to have a combination of tools for a better characterization of reaction products. It is also important to characterize the time-dependent nature of the catalyst library for developing a practical catalyst. Some catalysts have a significant induction period before they become fully active, and most catalysts deactivate over time. These properties will vary according to the reaction conditions, too. Some parallel screening schemes offer the capability of monitoring the reactions over time. For example, a multichannel fixed-bed reactor coupled with parallel GC and an array microreactor equipped with REMPI allow library screening over a prolonged reaction time. Many techniques such as mass spectrometry, IR spectroscopy, and other optical detection schemes can be applied in both homogeneous and heterogeneous catalysis. Techniques and tools for high-throughput catalyst screening are described in Chapter 10.

8.1. Oxidative Dehydrogenation of Ethane

The development of efficient heterogeneous catalysts for the gas-phase oxidative dehydrogenation of light paraffins is of particular interest because of the economic benefits of using paraffins directly as raw materials for the production of important base chemicals [125]. The low-temperature oxidative dehydrogenation of ethane to ethylene has been a research topic of consistent interest after the report of catalytic activity in the Mo – V – Nb – O system below 300 °C in 1978 [134, 135]. The optimum compositional range for these catalysts was reported to be $Mo_{0.61-0.77}V_{0.31-0.19}Nb_{0.08-0.04}$ [134, 135]. Researchers at Symyx Technologies have reproduced and improving these catalyst systems using combinatorial methods [136, 137].

The strategy reported is based on a three-step approach: In the primary screen thousands of catalyst formulations are generated by automated solution-based methods as arrays of thick films on 3-inch wafer plates by dispensing volumes on a nano- to microliter scale. The films themselves were prepared from sol – gel precursors that were deposited by automated solution deposition methods. The typical layout of a ternary library is shown in Figure 20. In this case the wafer holds a ternary ABC library consisting of two identical triangular matrices with 66 elements. The three corners in this library correspond to 100 % A, 100 % B, and 100 % C, respectively. Thus, the compositional increments are 10 % per matrix element for this kind of library layout.

Figure 20. Library design for a 3-inch quartz wafer

The libraries were then screened by using simultaneous mass spectrometry and photothermal deflection spectroscopy. The best catalysts were consecutively synthesized on a 25 – 50 mg scale for the secondary screen in parallel fixed-bed reactors. The secondary screen provides conversion and selectivity data for the catalysts under realistic operating conditions. Catalysts that performed well in the secondary screen are further evaluated in tertiary screens in bench-scale reactors with gram quantities of catalysts.

To demonstrate the reliability of combinatorial methods compared to larger scale experimentation, Symyx scientists could show that the primary screening data with conversions in the ppm range correlate well with bulk catalyst activity with percentage-level conversions.

For better catalyst performance, researchers at Symyx Technologies investigated additional libraries focusing on the most active area. This fine-tuning of the catalyst resulted in an ethane conversion of 12.8 % and an ethylene selectivity of 74.4 % at an optimal composition of $Mo_{73}V_{24}Nb_3$. Including Sb, Ca, and Li as dopants improved the catalysts even further. Under identical synthesis and reaction conditions, the optimal composition reported by Thorsteinson, $Mo_{73}V_{18}Nb_9$, converts 6.1 % at a selectivity of 83.2 % [136, 137].

8.2. Oxidative Dehydrogenation of Propane

Recently, Baerns, Senkan et al. reported the impregnation method of catalyst preparation coupled with multitube packed-bed reactors [122] and array microchannel reactors [138] within the framework of genetic algorithms [139] to find catalysts for the low-temperature oxidation of propane at low concentrations [126]. The catalyst libraries were prepared by an automatic liquid-dispensation system applying the incipient wetness method. A total of eight active components were selected as candidates for incorporation into TiO_2 or Fe_2O_3 as carrier materials.

Different generations of libraries consisting of mixtures of active elements at different compositions were prepared and then tested for their catalytic performance (conversion of C_3H_8 to CO_2) in both multitube packed-bed reactors [123] and array channel microreactors [138]. Significant propane conversions could be achieved at 50 °C. Catalysts providing propane conversions on the order of 90 % were also achievable at higher temperatures. The best catalytic materials were found to be rich in ruthenium; multimetal combinations were significantly superior [126].

More recently, the same group disclosed an evolutionary approach to optimize multimetal oxide (V_2O_5, MoO_3, MnO_2, Fe_2O_3, Ga_2O_3, La_2O_3, B_2O_3, and MgO) catalysts supported on α-Al_2O_3 for the oxidative dehydrogenation of propane to propene [131]. Thus, 56 catalytic materials were prepared for each generation, and this process was iterated five times. Both manual synthesis and robotic synthesis were used for the library preparations, and these catalytic materials were tested in parallel. For the best materials propene yields of 7 % (1st generation) to 9 % (5th generation) were achieved.

8.3. Catalytic Oxidation of CO and Reduction of NO

These two processes were studied at Symyx Technologies using catalyst libraries of metal alloys of Rh, Pd, Pt, and Cu [119]. $15 \times 15 \times 15$ triangular libraries containing approximately 2 – 4 µg of 120 independently prepared catalysts were prepared by deposition with fully automated radio-frequency sputtering techniques. Libraries with similar catalysts were also prepared by sol – gel-based methods.

The oxidation of CO was carried out in the presence of oxygen, and the production of CO_2 was determined by scanning mass spectroscopy. The amount of CO_2 produced followed the trend Rh > Pd > Pt, which is in good agreement with results from experiments with single-crystalline surfaces and supported catalysts.

In subsequent libraries, one of the noble metals was replaced by transition metals. In the library with Rh – Pd – Cu, the 1:1 composition of Cu – Rh showed activity very similar to that of pure Rh, and the catalyst with 93 % Cu and 7 % Rh maintains 40 % of the activity of pure Rh. In addition, Pt – Cu and Pd – Cu binaries show activity enhancements over the respective pure metals, whereby the enhancement is stronger at low than at high temperatures.

The oxidation of CO by NO was investigated along the same lines with the above-mentioned Rh – Pd – Pt library. The reaction was carried out at ambient pressure at various temperatures. As in the oxidation of CO by oxygen, the activity for the oxidation of CO by NO follows the trend Rh > Pd > Pt, similar to that reported in the literature for bulk catalysts.

9. Combinatorial Electrocatalysis

Electrochemical reactions play important roles, from energy production in fuel cells and batteries to industrially important processes such as the production of chlorine and the electrohydrodimerization of acrylonitrile to adiponitrile

Figure 21. Photographs of the different stages of discovery of a Pt – Rh – Os ternary alloy in array format with a quinine indicator
A) Image in white light. B) Fluorescence immage at low overpotential, identifying the most active region of composition space. C) Fluorescence image at high overpotential, where methanol oxidation occurs at every spot in the array

used in the production of nylon. Electrocatalysis deals with the modification of the overall rates of electrochemical reactions so that selectivity of these reactions and their yield and efficiency are maximized. The main focus is on the electron transfer reactions that take place at the electrode – electrolyte interface, with electrochemical parameters such as potential and current being the major driving force for the reaction.

9.1. Electrocatalysts for Fuel Cells

Fuel cell technology holds the promise of low-to zero-emission energy for power plants, backup generators, and application in the transportation sector. Fuel cells also will offer fuel efficiency on the order of 50 % or more. With increasing interest in fuel cells as alternative energy sources for stationary power, portable, and automotive applications, there is a need to develop new anode and cathode electrocatalysts. The cost of the current precious metal based electrocatalysts is a considerable hurdle to the successful commercialization of fuel cells.

The oxidation of methanol in fuel cells has been extensively studied for several decades. At present, however, the commercialization of the direct methanol fuel cell (DMFC) is beset by several problems, e.g., the low loading levels of noble metal catalysts, the high cost of the platinum catalyst, and catalyst poisoning by CO.

Mallouk, Smotkin et al. developed a rapid combinatorial synthesis and fluorescence screening method for the exploration of ternary and quaternary anode electrocatalysts for the DMFC (Figure 21) [108]. The authors created a library of 135 different ternary alloys by using automated ink-jet deposition of metal precursor aliquots onto a conducting fiber paper, followed by reduction of the metal salts with a borohydride reagent. These compositions were based on five transition metals (Pt, Ru, Os, Rh, and Pd). After treatment the libraries were immersed in an aqueous methanolic sodium sulfate electrolyte containing a fluorescent pH indicator. Screening was performed with a typical three-electrode cell (electrode array as working electrode, Pt counterelectrode, and saturated calomel reference electrode) by conducting a single potential sweep from cathodic to anodic potentials. It is expected that the pH will drop close to the regions where methanol is being oxidized. The conducting Toray paper was illuminated with an UV lamp, and observation of the highest fluorescent intensities due to local proton release (pH drop) upon electro-oxidation of methanol determined the catalytically most active spots on a given library. The composition performances were compared to Pt/Ru (50/50 atom %). The best composition was given as Pt/Os/Rh (60/25/15 atom %).

In addition, the same authors prepared, screened, and analyzed a 645-member electrode array of Pt, Ru, Rh, Ir, and Os consisting of 80 binary, 280 ternary, and 280 quaternary combinations [140–142]. The most active catalyst was found to be Pt/Ru/Os/Ir (47/29/20/4 atom %).

Scientists at Symyx Technologies have developed another combinatorial approach to the rapid synthesis and screening of fuel cell electrocatalysts. Libraries of alloy materials are synthesized directly onto an 8×8 electrode array (Figure 22). The electrode array consists of 64 individually addressable electrodes prepared on an insulating 3-inch quartz substrate by lithographic techniques. The electrode can be made from gold or titanium. Each electrode is approx-

imately 1.0 mm indiameter, and electrical contact is made with each electrode via a contact pad on the edge of the wafer. Electrocatalysts were synthesized by combination of magnetron sputtering or by parallel electroplating. The electrode array was then sealed to a Teflon cylinder that was filled with aqueous electrolyte. All 64 electrodes were therefore exposed to the same electrolyte solution. A common reference electrode and working electrode were immersed in the cell. The array was interfaced to a 64-channel potentiostat via a PCB interface, and the electrocatalytic performance of the resulting materials were tested by parallel monitoring of the of the current – voltage – time behavior of each individual electrocatalyst.

Figure 22. Symyx Technologies' electrode array consisting of 64 individually addressable electrodes prepared on an insulating 3-inch quartz substrate by lithographic techniques

The authors tested a number of catalytic concepts for the anodic electro-oxidation of methanol (DMFC), as well as the cathodic electroreduction of oxygen in aqueous acidic electrolytes [143]. It could be demonstrated that for known systems the electrochemical activity as measured directly on the thin-film samples on the addressable electrochemical array correlated with the activity of known powder samples.

9.2. Combinatorial Electrosynthesis

Ward et al. applied two different combinatorial approaches to study the electrochemical reduction of 1,4 benzoquinone to hydroquinone at organosulfur-modified gold electrodes [144]. The authors prepared an array of physically but not electrically isolated gold electrodes on a glass substrate. Monolayers of organosulfur reagents were prepared on selected electrodes on the 4×7 array by dispensing aliquots of hexanethiol or hexadecanethiol dissolved in ethanol at the respective electrodes. The array was subsequently rinsed and housed in a thin-layer electrochemical cell.

The first screening approach was based on a pH fluorescent assay, which was not sensitive enough. In a second approach the authors created an electrochemically addressable electrode array from which it was possible to directly measure the electrochemical activity by monitoring the current – voltage behavior at each individual electrode. In a serial manner the electrochemical reduction of benzoquinone was studied at each electrode by cyclic volatmmetry in which the potential of each electrode was cycled and the current measured. The authors proposed that this direct measurement of the electrochemical activity was more sensitive than the fluorescence screen in quantifying the benzoquinone reduction at the modified electrodes, and the results indicated that the activity in the library increases in the order of hexadecanethiol $<$ dodecanethiol $<$ hexanethiol $<$ gold, which indicates suppression of current with increasing alkanethiol chain length.

Yudin et al. demonstrated how combinatorial electrochemistry could be used in the electrosynthesis of small organic molecules [145]. The authors developed what they term a spatially addressable electrolysis platform (SAEP). Each electrochemical cell in the 4×4 array was equipped with a stainless steel cathode and a graphite rod anode. The cathodes were welded directly onto a stainless steel support that provided a common terminal for the current source. The authors explored the anodic oxidation of carbamates, amides, and sulfonamides leading to libraries of α-alkoxycarbamates, α-alkoxyamides and α-alkoxysulfonamides, respectively. Also, the intramolecular cyclization of hydroxyamides yielding heterobicyclic compounds and the generation of vicinal diamines by the reductive hydrocoupling of aldimines were achieved.

Yudin et al. generated libraries of catalytic materials on electrode surfaces by the copolymerization of bithiophene and pyrrole con-

taining TEMPO (2,2,6,6-tetramethilpiperidin-1-yloxy) catalysts [146, 147]. Diversity was created by electrochemical copolymerization and creating surfaces with different ratios of bithiophene/pyrrole. These catalyst films were utilized in the electrochemical oxidation of primary alcohols to aldehydes, whereby cyclic voltammetry was used to screen the catalytic activities of the modified electrodes.

Hillier et al. applied a scanning electrochemical microscope to characterize the oxidation of hydrogen on a polycrystalline platinum surface [148, 149] This technique could be utilized for the direct measurement of the rate constant for hydrogen oxidation and the reactivity mapping of heterogeneous electrodes consisting of catalytic and noncatalytic domains.

10. High-throughput Screening Tools for Catalysis

The process of discovering new catalysts or materials from a large pool of potential candidates requires a reliable and robust screening process. Traditionally, this process represents a bottleneck in the discovery effort, especially if large libraries of potential catalysts or materials have already been synthesized or prepared. The first step in combinatorial catalysis, like all materials design, involves the identification of a specific chemical transformation of interest. A collection of potential catalysts, prepared from a set of chemically diverse ligand sets and metal precursors, are combined in a parallel or combinatorial fashion and screened for activity in a high-throughput primary screen. Although the large volume of potential catalysts examined in a primary screen typically allows only relative activity to be established, the goal at this stage of discovery is to identify promising lead catalysts worthy of further investigation and follow up. Lead materials are then further examined in a high-throughput secondary screen designed to screen for specific trends in the physical and chemical properties in greater detail and typically at a slightly lower throughput than the primary screen. The information obtained from the secondary screen is then used to prepare additional generations of catalysts that can be optimized into a superior catalyst worthy of commercialization.

Typically, the information necessary to classify new materials cannot be obtained from a single characterizing device. Therefore, a series of high-throughput screening tools are employed at various stages in the combinatorial process. While a large number of automated commercial systems exist for high-throughput analysis of microliter samples for medical and pharmaceutical applications, the majority of the screening tools necessary for advanced materials research are custom-made instruments. Conventional analytical tools such as mass spectrometry, gas [150] and liquid chromatography, electrophoresis,[151–153], Raman [154] and NMR spectroscopy, X-ray fluorescence microprobe analysis [133], and X-ray diffraction [155] have been automated and redesigned for rapid serial measurements of hundreds of samples per day [156]. A number of reviews on high-throughput screening techniques are available [17, 18, 20, 21, 102, 157–159]. Several examples of novel high-throughput screening systems are listed in the following:

1) Infrared
   a) IR thermography [34, 115, 116, 160–166]
   b) High-throughput infrared spectroscopy [167–170]
2) Optical
   a) Colorimetric assay [108, 132, 171–179]
   b) Resonance-enhanced multiphoton ionization (REMPI) [112, 130, 138]
   c) Photothermal deflection [125]
   d) Circular dichroism [180, 181]
3) Mass spectrometry
   a) Scanning MS [120, 122, 182, 183]
   b) Electrospray MS using mass tags [184, 185]
4) Electronic methods
   a) Electrode arrays [119, 144, 145, 147, 148, 186]
   b) Solid-state temperature sensors [187]
   c) Solid-state gas sensors [188]
5) Eelectrophoresis
   a) Capillary array electrophoresis [151–153]

11. Combinatorial Solid-State Materials Science

The application of combinatorial technologies towards discovery in solid-state materials sci-

ence has exploded during the past few years. The central challenges faced in adaptation of high-throughput techniques are related to the ability to prepare solid-state materials in an array format while retaining key physical properties. To this end, significant technological advances have been made in the areas of the synthesis and characterization of solid-state materials by adaptation of conventional solution and vapor-phase synthetic techniques. A wide variety of high-throughput characterization methods for arrays of solid-state materials are now available, including optical and structural techniques such as electro-, cathodo-, and photoluminescence, as well as X-ray diffraction. Using these techniques, significant advances continue to be made in the areas of superconductivity, ferromagnetic superconductors, magnetoresistant materials, dielectric and ferroelectric materials, and various luminescent materials.

11.1. Materials Library Synthesis

One of the biggest challenges posed by the high-throughput synthesis of solid-state materials in an array format is the need to maintain relevant bulk physical properties. To this end, a variety of synthesis techniques based on solution deposition or thin-film deposition have been developed for the preparation of libraries of solid-state materials [189–194]. The choice of synthesis technique is based on the material being prepared as well as the primary screen employed after synthesis. For example, by modifying technologies similar to those used to make integrated circuit (IC) chips, materials libraries or integrated materials (IM) chips were first developed and utilized by Schultz et al. [10]. Regardless of the synthetic technique utilized, a library of solid-state materials must typically undergo thermal processing involving temperatures in excess of 400 °C to complete the synthesis of the target materials. Such high temperatures required the development of thermally stable substrates that allow the preparation of two-dimensional, spatially addressable arrays of solid-state materials.

11.1.1. Vapor Deposition Techniques

Vapor deposition is commonly used in the semiconductor industry to deposit thin films of material onto a substrate. Vapor deposition techniques that have been utilized in combinatorial library synthesis include sputtering [21, 195, 196] and thermal evaporation [197–201], electron-beam evaporation [202, 203], pulsed laser ablation [21, 204, 205], ion-beam implantation [206–209], molecular-beam epitaxy [210–213], and chemical vapor deposition [214, 241].

One of the most straightforward thin-film approaches is the continuous-composition spread (CCS) technique, which utilizes two or three off-axis sources to co-deposit material on a substrate [196]. This technique relies on the non-uniform deposition of materials formed by the geometric arrangement between the sources and the substrate. The relative concentration of each component at a specific location on the substrate decreases with the distance from the source. As materials spread from the sources, they mix in the vapor and are deposited on the substrate with atomic-level mixing, which reduces or eliminates the need for high-temperature post-processing of the library. This technique is also amenable to the isolation of metastable or low-temperature phases that are crystalline on deposition. The lack of precise stoichiometric control and limited compositional range has relegated this technique primarily to optimization and exploration of systems with only two independent variables.

Another technique frequently employed for combinatorial materials science utilizes a vacuum deposition system with several source materials, used in conjunction with masking techniques employing physical or shadow masks, movable shutters, or photolithography [10, 189, 190, 215–218, 253]. Masking allows for controlled deposition of different materials sequentially or simultaneously on particular areas of the substrate. The design of the masks and the sequence in which they are employed determine how the materials are deposited at a given location on the substrate. By altering the sequence, time, and rate of deposition, it is possible to control the exact chemical composition of each element in the library.

Figure 23 illustrates the efficiency of such a masking approach, whereby a compositionally variant array of materials can be constructed by using physical or photolithographic masks. In

Figure 23. The quaternary masking system uses six fractal masks, each of which can be rotated by 90° to allow four choices of materials at each level

this example, a portion of the substrate is alternatively covered with a mask and subjected to vapor deposition of a particular component of $A_kB_mC_nO_x$ until each component has been deposited. Gradient deposition is often employed to allow systematic control over variations in the stoichiometry for each component and the thickness of the depositions. The geometry and positional orientation of the masks can be varied in many ways, and this allows the phase space to be systematically and exponentially constructed. For example, in the hypothetical phase space of $A_kB_mC_nO_x$ in Figure 23 the use of four different components for A, B, and C utilizing four dopant components for A and B results in 4^5 or 1024 unique compositions.

Thin-film deposition methods are synthetically quite versatile; they have progressed to enable atomic- and molecular-layer epitaxy and offer the ability to construct artificial lattices, epitaxial overlayers, and patterned films of a variety of materials. Dopants are usually sandwiched between layers of the host material to avoid evaporation and to assure proper interdiffusion. Subsequent thermal processing is usually required to ensure the formation of single-phase materials in the library of materials or devices [189, 219, 220, 250]. Physical properties of the materials can be subsequently screened with contact or noncontact screening probes. The number of compounds that can be simultaneously synthesized by this technique is limited by the spatial resolution of the masks (up to 10^6 per square inch if photolithography is used) and by the degree to which microscale synthesis can be performed.

Combinatorial thin-film techniques such as those described above have been utilized in the discovery of a variety of new electronic materials. For example, Pessaud et al. utilized pulsed laser ablation of two compound targets made of superconducting $YBa_2Cu_3O_7$ (YBCO) and the double-chain insulator $MCuO_2$ (M = Ca, Sr) to create new metastable superconducting materials [204].

New multiwavelength-emitting chips for applications in wavelength-divisible multiplexing (WDM) have also been explored. For example, Liu et al. succeeded in growing single quantum wells of $Al_{0.35}Ga_{0.65}As$/GaAs on GaAs (001) substrates by MBE and were able to generate more than 20 different wavelengths from a single chip [207].

Amorphous materials have been investigated in a combinatorial optimization of hydrogenated amorphous silicon (a-Si:H) based thin-film transitor (TFT) devices by Koinuma et al. using plasma-enhanced chemical vapor deposition [214].

11.1.2. Alternative Library Synthesis Techniques

The synthesis of many materials such as zeolites, polymers, polycrystalline phosphors, and many other oxides and sulfides is best accomplished by using solution-phase methods. When applicable, solution-phase methods allow the creation of a large number of libraries at a significantly lower capital investment compared to automated vapor deposition equipment. Additionally, solution-phase methods can often result in improved compositional control over thin-film techniques. One significant complication associated with materials discovery in thin-film format is the occasional lack of correlation with bulk properties due to differences caused by film microstructure, strain, and so on. Physical and chemical properties of materials prepared by solution techniques generally show excellent correlation with bulk properties, regardless of the quantity of material prepared. This is particularly advantageous from the standpoint of enabling the correlation of properties of materials synthesized in a library format with those prepared in bulk by traditional solid-state synthesis.

A major advantage of solution techniques is that they allow mixing at the molecular level, which reduces the need for high-temperature interdiffusion and also facilitates the isolation of metastable phases. For example, sol – gel techniques are frequently employed in the preparation of arrays of a variety of inorganic nanostructured materials such as phosphors [221], oxide semiconductors [222], and polymer/vanadium oxide nanocomposites [223]. The use of soluble metal precursors such as metal alkoxides in the fabrication of such arrays makes the sol – gel approach particularly amenable to combinatorial methods [221, 222].

Solution-based techniques can also be use to prepare highly dense arrays of materials. For example, Xiang, Schultz et al. have demonstrated that a scanning multihead ink-jet delivery system can be used to perform automated microsynthesis of solid-state libraries. Using this technique, deposition volumes on the order of 500 nL can be dispensed rapidly with an accuracy better than 99 % [190, 224]. The system has been successfully used to generate libraries with 100 members per square inch, and a system capable of generating 1000 members per square inch is under development.

The application of solution-based techniques in the hydrothermal synthesis of materials such as multicomponent zeolites has also been explored. To this end, a variety of reactors for hydrothermal synthesis have been designed to accommodate the requirements of small-scale synthesis [225–227]. For example, Akporiaye et al. have reported the design of stackable, miniature, multi-autoclave reactors that house up to 100 reaction wells with volumes of ≤ 0.5 mL [225]. Using a battery of these reactors, the ternary phase diagram for the $Na_2O - Al_2O_3 - SiO_2 - H_2O$ system was successfully reproduced with total sample volumes ≤ 0.5 mL. Klein et al. have reported the construction and testing of an even smaller reactor, that employs a silicon substrate for hydrothermal synthesis and can achieve reaction volumes on the order of 2 μL. Libraries of materials can then be analyzed with an automated X-ray diffraction instrument [226]. The success of these and other approaches clearly suggest that general microscale synthesis of materials by hydrothermal synthesis is tenable.

The adaptability of solution-based combinatorial strategies towards the preparation of nanoclusters and surfaces exhibiting nanoscale morphologies has also been demonstrated. For example, Baker et al. have described the synthesis of surfaces exhibiting nanoscale variation in mixed-metal compositions and architecture [228]. Continuous or stepped gradients in the size and number density of surface features can be generated simultaneously over different regions of a single substrate. For example, a library of Ag-clad colloidal Au arrays was prepared in which the coverage of colloidal Au and the extent of the reductively deposited Ag coating were varied in an attempt to optimize the enhancement factor for surface enhanced Raman scattering (SERS) [228, 229]. In one application of nanoscale-based synthesis, Wright et al. have shown that combinatorially derived peptide and peptidomimetic ligands based on phytochelatins can stabilize CdS nanoclusters [230–232].

Lithographic masking techniques analoguos to those described for the preparation of thin-film arrays of materials have been used in conjunction with solution-based approaches. For example, Vossmeyer et al. have developed a scheme for generating complex, spatially sep-

arated patterns of multiple types of semiconducting and/or metallic nanocrystals employing photolithography. The technique involves the stepwise preparation of multiple-particle arrays based on lithographic patterning of amino-functionalized organic monolayers that contain a photolabile protecting group covalently bound to a substrate with an SiO_2 surface. The substrate is photolyzed, which results in deprotection of the unmasked areas, and then treated with amine-stabilized nanoparticles of metals that bind to the exposed SiO_2 surface. This technique was used iteratively to prepare binary micropatterns consisting of Pt or Au and highly luminescent CdSe/CdS core/shell nanocrystals [194].

Many new advanced materials ranging from magnetic materials to bulk metallic glasses involve alloying multiple elements to control both intrinsic and extrinsic properties. Permanent magnets, for example, may contain a dozen or more elements to control grain boundaries and domain wall movement. Cohen-Adad et al. utilized a melting-zone technique to investigate AlCo and AlCoFe alloys [233]. In their method, source materials are cut into wedges and then welded together into a bar. The bar is then placed in an alumina crucible and drawn through a horizontal zone furnace to facilitate mixing. The resulting bar is diced into pieces, and the composition at each point along its length is measured by microprobe analysis. The morphology and crystal structure of the materials were investigated with optical microscopy, differential thermal analysis, and X-ray diffraction. Inoue has reviewed similar techniques used to search for new glasses, which typically contain five or more elements to inhibit crystallization [234].

11.2. High-Throughput Screening for Materials

The large numbers of compounds and the speed with which they may be prepared by combinatorial synthesis require commensurate automated high-throughput characterization. Typically, multiple methods of characterization are required to adequately screen new materials during primary, secondary, and higher order screening. To this end, a series of high-throughput screening tools are often employed at various stages in the combinatorial process to create a screening hierarchy. The screening tools required for high-throughput characterization are frequently custom-made instruments, often incorporating or adapting technologies developed for conventional materials characterization. Conventional analytical tools such as mass spectrometry, gas and liquid chromatography, optical and NMR spectroscopy, X-ray fluorescence microprobe analysis [235], and X-ray diffraction have been automated and redesigned for rapid serial measurements of hundreds of samples per day [156, 236].

11.2.1. Optical Screening

Optical screening methods, where applicable, offer high-throughput noncontact screening for combinatorial libraries. Optical screens typically involve a laser or fiber-optic probe that is serially scanned across a library, or utilize cameras capable of imaging library elements in parallel. In studies of luminescent materials, high-throughput screens using UV-excited photoluminescence allow quantitative measurement of chromaticity and relative extrinsic efficiencies [110, 111]. Optical transmission and reflection measurements have also been utilized to determine the band gap of various oxide thin films, as well as to estimate band gaps for thermoelectric and photovoltaic materials [213, 237]. Lastly, an apparatus for the measurement of electro-optic coefficients of thin-film samples that functions by measuring the polarization modulation of light from a HeNe laser passing through a sample has been described by Xiang. This technique can be used to determine electro-optic coefficients of materials in a thin-film format [10].

11.2.2. X-Ray Characterization

Structural characterization by X-ray diffraction plays a critical role in conventional synthesis of solid-state materials and is equally important in high-throughput methods. Several groups have created instruments capable of X-ray microdiffraction on samples in array format. [235, 236]. This has been made possible by the use of intense X-ray sources (rotating anode or synchrotron), and focusing mirrors that collimate an X-ray

Figure 24. Schematic representation of an X-ray microprobe synchroton beamline capable of producing a $3 \times 20\,\mu m^2$ X-ray spot on a sample in the library array

beam onto a small spot within the dimensions of the sample size in the array (Figure 24). However, data collection times for the measurement of a significant number of library elements can require hours (rather than minutes). Moreover, exploratory libraries are typically mixed phases in nature, whose complicated analysis has yet to be dealt with efficiently.

11.3. Applications of Materials

11.3.1. Superconductivity

One of the first demonstrations of combinatorial thin-film materials exploration by Schulz et al. involved the preparation of libraries of superconducting copper oxide thin films by sputtering several metal oxides in sequence onto an inert single-crystal support of either MgO or $LaAlO_3$ [10, 238, 190]. Arrays containing different combinations, stoichiometries, and deposition sequences of $BaCO_3$, Bi_2O_3, CaO, CuO, PbO, $SrCO_3$, and Y_2O_3 were generated. The superconductivity of each sample was evaluated by measuring its resistance as a function of temperature, with an array of probes that analyze 64 samples at a time. Superconducting films of $BiSrCaCuO_x$, $BiPbCaSrCuO_x$, and $YBa_2Cu_3O_x$ were identified with critical temperatures in the range of 80 – 90 K.

Xiang et al have developed a scanning evanescent microwave microscope (SEMM) capable of nondestructive and quantitative mapping of electrical impedance with submicrometer resolution [241, 242]. Unlike conventional four-probe methods, the SEMM is a noncontact method, which eliminates dependence on contact resistance and interfacial effects. The microscope is routinely used for characterization of linear and nonlinear dielectric constants of ferroelectrics and dielectrics.

Alternative sample pooling is used in high-T_C superconductor research [243, 244]. Superconductivity is one of the few electronic properties that can be measured when samples are pooled (mixed together) in a single vial. In this method, several compositions are synthesized separately and then mixed together to form a single sample. The presence of a Meissner fraction indicates the presence of superconductivity in at least one of the compounds in the mix, the identity of which must be determined by individually measuring each of the components in that particular mix.

Bozovic et al. utilized a sophisticated composition-spread MBE system, an ozone source, an electron microscope (LEEM/LEED/PEEM system), time-of-flight ion scattering and recoil spectroscopy, and scanning quartz microbalances in a search for new materials for oxide electronics [245].

11.3.2. Ferromagnetic Semiconductors

Ferromagnetic semiconductors are important materials for spin-based electronics in which the correlation between charge and spin is used

to generate spin-dependent electronic functionality such as giant magnetoresistance and spin field effect transistors. Among known materials, Mn-doped GaAs is the most promising for practical applications because it has the highest magnetic ordering (Curie) temperature ($T_C \approx 100$ K. The search for new ferromagnetic semiconductors has led to the investigation of dilute magnetic oxides. Kionuma et al. have applied a combinatorial approach to the search for new ferromagnetic semiconductors by adding small amounts of cobalt to the anatase form of TiO_2 [246]. TiO_2 and $Ti_{0.5}Co_{0.5}O_2$ ceramic targets were ablated with a KrF excimer laser in a combinatorial laser molecular beam epitaxy system [247]. The ferromagnetic ordering temperature was estimated to be in excess of 400 K, a substantial increase over the Mn-doped GaAs compounds.

11.3.3. Magnetoresistant Materials

The preparative combination of thin-film deposition and physical masking techniques was used by Xiang et al. in the discovery of new cobalt oxide magnetoresistance materials [109, 248, 249]. Magnetoresistance is the variation of electrical resistance with an applied magnetic field. Materials with particularly large magnetoresistance properties are useful in high-density magnetic storage technology such as read heads for computer hard drives [250]. Colossal magnetoresistance (CMR) was first discovered in Mn-based perovskites $(La,R)_{1-x}A_xMnO_{3-\varepsilon}$, where R is a rare earth element, and A is Ca, Sr, or Ba. Two identical 128-member libraries of composition $Ln_xM_yCoO_z$ were synthesized on $LaAlO_3$ single crystals, where Ln = $(La, Y)^{3+}$ and M = $(Ca, Sr, Ba, Pb)^{2+}$. The two libraries were annealed and sintered under different conditions, and one showed an overall decrease in magnetoresistivity, which highlights the fact that in combinatorial materials synthesis, post-deposition processing conditions represent important variables. Large magnetoresistance (Δ; $R/R(0) > 5$ %) was measured in $La_x(Ba,Sr,Ca)_yCoO_z$ samples, while Y-based samples exhibited much smaller magnetoresistive effects.

11.3.4. Dielectric and Ferroelectric Materials

Driven by the current trend toward the continued miniaturization of electronic devices, improved thin-film insulators are needed in, for example, dynamic random access memory (DRAM) computer chips. Using the composition spread technique (CCS), van Dover et al. from Lucent Technologies have reported new dielectric thin-film materials that have higher dielectric coefficients than amorphous silicon dioxide (a-SiO_x), the insulating material most commonly used today [242, 251–253]. The CCS technique involves the co-deposition of three different reagents onto a substrate from a triangular arrangement of targets. Van Dover et al. used off-axis RF magnetron sputtering guns to codeposit a continuous ternary composition variation of Zr, Ti, and Sn on a TiN-coated Si wafer [251, 253]. A continuous thin film was obtained, and the position-related composition was inferred by using Rutherford backscattering spectroscopy. To isolate the optimum thin-film transistor candidate ($Zr_{0.15}Sn_{0.3}Ti_{0.55}O_{2-\varepsilon}$), more than thirty combinatorial libraries were synthesized and evaluated at a rate of approximately one per day.

Combinatorial approaches have been applied by Xiang et al. to ferroelectric materials in which the effects of transition metal dopants on the dielectric coefficient and tangent loss of a library of thin films of $(Ba_xSr_{1-x})TiO_3$ (BST) were determined [254, 255]. Ferroelectric materials are being widely used in the development of new microwave devices such as frequency agile filters, phase shifters, and tunable resonators, and $(Ba_xSr_{1-x})TiO_3$ compounds have been intensely studied. Four libraries of 256 differently doped thin films of $(Ba_xSr_{1-x})TiO_3$, where $x = 1, 0.8, 0.7$, and 0.5, were generated on a $LaAlO_3$ substrate. These four hosts were then doped with different combinations of different metallic elements. The resulting dopant map for the $(Ba_{0.8}Sr_{0.2})TiO_3$ quadrant is shown in Figure 25 (see next page).

Appropriate post-annealing afforded high quality epitaxial thin films, comparable to those made by conventional in situ methods from stoichiometric targets on hot substrates. The rapid, quantitative and nondestructive characterization of the microwave dielectric coefficient and loss tangent of samples in the library was achieved

Figure 25. Dopant map for the $(Ba_{0.8}Sr_{0.2})TiO_3$ quadrant of a ferroelectric thin-film library; the same map applies to the other three quadrants containing different host materials. A quaternary masking scheme with four masks was used to deposit 256 differently doped thin films of $Ba_xSr_{1-x}TiO_3$ $(0.5 < x < 1)$ on a 2.54×2.54 cm $LaAlO_3$ substrate.

with a scanning-tip microwave near-field microscope at 1 GHz, and the results were found to be consistent with measurements made with interdigital electrodes [21, 239, 256–261].

Subsequently, the effects of dopants on device performance were evaluated by incorporating a layer of the doped dielectric $(Ba_xSr_{1-x})TiO_3$ in a parallel-plate capacitor library between Pt and $La_{0.5}Sr_{0.5}CoO_3$ electrodes [262]. Multilayer device structure libraries of 240 different host/dopant combinations were epitaxially synthesized with sharp interfaces from amorphous layers on a $LaAlO_3$ substrate. Since the conventional techniques of high-temperature, in situ epitaxial thin-film growth cannot be used for combinatorial library synthesis, Xiang et al. developed a synthesis method to form epitaxial multilayers from amorphous layers deposited at room temperature using pulsed laser deposition (PLD).

11.3.5. Luminescent Materials

The combinatorial methodology of thin-film deposition and masking techniques to create materials chip libraries has quickly found applications in the discovery and optimization of luminescent materials. Despite many years of intensive research, fewer than 100 useful commercial phosphor materials have been discovered by conventional one-at-a-time synthesis and testing. Phosphor materials with high quantum efficiencies find application in display technologies such as cathode ray tubes (CRTs) and are of great importance for developing improved plasma, field emission, and electroluminescent flat-panel displays, and lighting [263]. Oxides are attractive host materials for the development of advanced phosphors due to their ease of synthesis and stability. For example, the efficient refractive oxide phosphor, $Y_2O_3{:}Eu^{3+}$ (red), $Y_3Al_5O_{12}{:}Tb^{3+}$ (green), and $BaMgAl_{10}O_{17}{:}Eu^{2+}$ (blue) have found applications in tricolor lamps, projection TVs, and plasma displays.

Symyx Technologies' red phosphor $Y_{0.845}Al_{0.07}La_{0.06}VO_4{:}Eu_{0.025}$, with a quantum efficiency approaching those of existing commercial red phosphors, was discovered in

a library of 25 000 different compositions produced by using electron-beam evaporation to deposit thin films onto a 3-inch silicon wafer [110]. In this discovery library, four constant-thickness columns were first deposited, consisting of SnO_2, V_2O_5, $Al_2O_3 + V_2O_5$, or Al_2O_3. On top of these layers were deposited four rows of linearly varying thickness of La_2O_3, Y_2O_3, MgO, and $SrCO_3$ to create 16 host lattice subregions. Finally, within each of the 16 subregions linearly varying thickness of the rare earths Eu_2O_3, Tb_4O_7, Tm_2O_3, and CeO_2 were deposited, resulting in approximately 600 different chemical compositions per square centimeter (Figure 26). High-throughput screening for UV-excited photoluminescence was performed by photographing the visible emission of the library with a charge-coupled device (CCD) camera while exciting with a 254 nm broadband source. To optimize the best host compositions of the Eu-doped red phosphors, $Y_{1-m}Al_mVO_4$, identified in the initial high-density exploration library, a second library was deposited on a triangular grid, which included La as a third host component to explore all possible $Y_{0.95-m-n}Al_nLa_mVO_4$:$Eu_{0.05}$ compounds. The maximum intensity with red chromaticity corresponds to the phosphor composition $Y_{0.82}Al_{0.07}La_{0.06}VO_4$:$Eu_{0.05}$. The activator concentration in this lead host was subsequently optimized with a third library in which the Eu^{3+} concentration was varied, resulting in the final optimized composition $Y_{0.845}Al_{0.07}La_{0.06}VO_4$:$Eu_{0.025}$ with improved red chromaticity ($x = 0.67$, $y = 0.32$) compared to the more orange standard commercial red phosphor $Y_{1.95}O_3$:$Eu_{0.05}$ ($x = 0.64$, $y = 0.35$). Synthesis of bulk samples by conventional methods confirmed the performance of the newly identified phosphor composition.

The group from Symyx Technologies followed the red vanadate phosphor with a report on a novel luminescent oxide, Sr_2CeO_4 with a bluish white emmision [111].

Xiang et al. prepared several 128-member libraries of aluminates of the formula $Gd(La,Sr)AlO_x$ doped with rare earth activators. The combinatorial libraries were used to survey the phosphorescence of a wide range of oxide compositions under a variety of processing conditions [264].

Subsequently, Xiang et al. demonstrated that a scanning multi-inkjet delivery system can be used to achieve results identical to the vapor-deposited libraries [265].

Figure 26. Deposition map (left) of a diverse phosphor discovery library; the thicknesses of the various materials deposited on a 3-inch silicon wafer are shown. Photograph (right) of the UV-excited photoluminescence of the discovery library containing approximately 25 000 different compositions. In this library, novel efficient red and blue phosphor compositions were identified and subsequently optimized in focus libraries.

Libraries of thin-film phosphors $(Gd,La,Y)_m(Ta,Zr,W,Mo,Zn)_n(Al,Mg,Sr)_kO_x$:$(Tm,Eu,Tb,Ce)_y$ (with $0 \leq m$, n, $k \leq 1$, $0.005 \leq y \leq 0.1$) were generated by Sun and Xiang using sequential RF [266]. A new red phosphor with the composition $(Gd_{1.54}Zn_{0.46})O_{3-\delta}:Eu^{3+}_{0.06}$ was claimed.

Schultz et al. used RF/DC sputtering to prepare three 1024-member libraries of silicate and gallate host materials on Si substrates, each library entity containing a number of different dopants [218].

Thin-layer organic light-emitting devices (OLEDs) are an emerging technology that is beginning to be commercialized in flat panel displays. To develop this technology further, it is important to optimize different materials properties, layer thicknesses, deposition parameters, and layer compositions under comparable and reproducible conditions. A combinatorial approach has been developed to create libraries of different OLEDs in order to screen and optimize device parameters with respect to power efficiency, photometric efficiency, and current – voltage characteristics [197–200, 267]. Schmitz et al. used a combinatorial approach to optimize the Alq_3 (8-hydroxyquinolinlato – Al^{III}) layer thickness on top of a constant-thickness hole-transport layer (HTL) to resolve whether an additional electron-transport layer (ETL) can further enhance device performance [200].

12. Organic Materials and Polymers

The application of combinatorial chemistry holds great promise in the discovery of novel functional organic materials. The current emphasis is on finding materials that either selectively bind small organic molecules or have improved physical and mechanical properties.

12.1. Schiff Bases for Nonlinear Optical (NLO) Materials

An investigation of the combinatorial synthesis procedures needed for the rapid formation of large libraries of polar compounds for the preparation of nonlinear optical (NLO) materials has been described by Nesterov et al. [268]. The structural characteristics of the Schiff base products (i.e., donor and acceptor groups connected to a π-conjugated chain) are believed to have potential as NLO or electro-optical materials. Nesterov et al. created a test library using four amines and two aldehydes as the building blocks for eight potential polar Schiff bases. Acid-catalyzed condensation of a set of electron-rich cinnamaldehydes with four electron-poor anilines generated a small library of eight Schiff bases. Crystalline precipitates were observed in every reaction, and crystals suitable for X-ray diffraction were obtained from all but one of the reactions. Five crystal structures were determined, all with centrosymmetric space groups that preclude the compounds from being NLO candidates.

12.2. Artificial Receptors for Small Organic Molecules

Since the rational design of nanoporous materials and their inclusion cavities based on molecular structures is difficult, combinatorial methods were implemented to find superior lattice inclusion compounds [269]. When screened against a guest molecule (*i*PrOH), seventeen ammonium carboxylate host compounds were discovered from a combinatorial library of 100 salts formed by mixing ten commercially available amines and ten carboxylic acids. One host compound was identified that forms inclusion compounds with 25 different organic solvents. Application to chiral recognition by the proper choice of amines and carboxylic acids to form a variety of host compounds is under investigation.

Leblanc et al. applied combinatorial principles to surface chemistry by synthesizing and screening libraries of amphiphilic lipid molecules [270]. At the air – water interface, the hydrophilic polar moiety of these molecules is embedded into the water phase and the hydrophobic alkyl chain is oriented towards the air phase. When compressed at the interface, the amphiphilic molecules move and assemble into organized supramolecular structures, known as Langmuir monolayers. The polar moiety was functionalized with a peptide library such that the self-assembly of these functional lipids formed proteinlike supramolecular structures. One library with 250 members and three

sublibraries of 54 members each were assayed for molecular recognition of maltose and other sugar molecules. One sublibrary, containing both polar charged (Glu) and aromatic (Tyr) amino acid residues, was identified that selectively bound maltose but not D-glucose and sucrose.

12.3. New Materials for the Separation of Enantiomers

Given the enormous demand for enantiomerically pure compounds in the pharmaceutical field, novel chiral stationary phases (CSPs) for high-performance liquid chromatography (HPLC) were developed by combinatorial means [271]. Fréchet et al. prepared a model library of chiral stationary phases (selectors) for HPLC by attaching a small model library of 36 chiral compounds that were obtained from three L-amino acids and 12 aromatic amines to synthetic polymer beads (Figure 27) [272]. After the entire on-bead library of selectors was packed into a HPLC column, selectivity was assayed by injecting various racemates of chiral targets. Despite the presence of 36 mixed selectors, racemic DL-(3,5-dinitrobenzoyl)leucine diallylamide was separated. A deconvolution process was used to determine which of the 36 selectors in the HPLC column was the most powerful. In contrast to the "one-column, one-selector" approach, which would require the preparation and testing of 36 chiral stationary phases, this combinatorial scheme requires the preparation of only 11 columns for the discovery of the most selective material. With the same approach, a library of 240 selectors could be deconvoluted with only 17 columns.

Selector: R^1 = alkyl, R^2 = aryl

= poly(2-hydroxyethyl methacrylate-*co*-ethylene dimethacrylate)

Figure 27. Model library of chiral stationary phases (selectors) for HPLC

Two groups applied the principle of reciprocity to the identification of new CSPs [273–275]. This approach is based on the following assumption: if a ligand of the stationary phase is selective toward an analyte, then the same analyte immobilized on the proper support should result in a stationary phase that is very likely to be selective toward the original ligand [276]. Following this principle, the chiral substrate (*S*)-(3,5-dinitrobenzoyl)leucine acted as an "inverse" selector and was immobilized on synthetic polymer beads [273]. A library of 108 racemic 4-aryl-1,4-dihydropyrimidines (DHPM) was screened against the "inverse" selector by observing the enantioselectivity for resolution. The best candidate was then attached to monodisperse macroporous beads to prepare the new polymer-based chiral stationary phase which proved efficient in the resolution of several analytes.

A different approach is to synthesize parallel combinatorial CSP libraries with up to 200 members and screen them for their ability to resolve a racemate of the analyte [277–279]. These libraries of potential selectors typically consist of immobilized dipeptides and a capping group. Racemic analyte is then added to each member of the library and allowed to equilibrate. The enantiomeric ratio of the analyte in the supernatant is analyzed after the equilibration period by circular dichroism measurements or other methods. A selective absorption of one of the two enantiomers to the resin is indicative of a chiral selector.

Welch et al. introduced a method for rapid LC/MS screening of chiral stationary phases based on the use of isotopically labeled enantiomers [280]. "Pseudoracemates" made up of a pair of isotopically differentiated pseudoenantiomers were prepared and screened against different CSPs. The enantioenrichment of the supernatants can be rapidly estimated by comparing the MS abundance of the ions corresponding to each of the pseudoenantiomers.

A visual screen for identifying chiral selectors was introduced by Still et al. [281]. The idea was to treat an equimolar mixture of a blue L-amino acid and a red D-amino acid with a library of chiral selectors on synthesis beads, each of which carries a different selector (Figure 28). Highly enantioselective binding results in red or blue beads, whereas unspecific binding yields brown beads. The reddest and the bluest beads found in the assay were picked and decoded to

Figure 28. Enantiomeric probe labeled with different dyes

determine the structure of the bound chiral selector.

12.4. Molecular Imprinting

Molecularly imprinted polymers (MIPs) are another class of artificial receptors for small organic molecules. Their binding performances give these materials great potential in combinatorial approaches as recognition matrices for the screening and rapid selection of ligands from a combinatorial library [282–284]. In molecular imprinting recognition sites are generated within a macromolecular matrix by use of a molecular template in a casting procedure [285]. The selected ligand (print molecule) is first allowed to interact freely in solution by bond formation with one or more functional monomers. The resulting adducts are subsequently copolymerized with a large excess of cross-linker to give a rigid, insoluble polymer. Following extraction of the print molecule, specific recognition sites are left in the polymer. The technique has been applied to the screening of a combinatorial steroid library [282], and a combinatorial library of molecularly imprinted polymers has been tested in chiral separations [284].

In 1999 Takeuchi et al. reported a rapid combinatorial approach to synthesize and evaluate artificial receptors [286]. The preparation of the MIPs was automatically performed by using programmable liquid-handling equipment with a new in situ molecular imprinting protocol. The freshly synthesized MIP library (polymer films) was then subjected to a primary screening to estimate the affinity of the template to the resultant polymer. A secondary screening on purified MIPs then allows for a more precise evaluation of the affinities and selectivities of the new materials. MIPs that are artificial receptors for triazine herbicides ametryn and atrazine were prepared by the combinatorial molecular imprinting approach by using variable amounts of two functional monomers, methacrylic acid (MAA) and 2-(trifluoromethyl)acrylic acid (TFMAA), as well as ethylene glycol dimethacrylate as a cross-linker and AIBN as the polymerization initiator.

12.5. Polymer Topologies and Functionalization

Combinatorial approaches have also been applied to polymer chemistry. For example, a small library of 112 strictly alternating copolymers (0.2 g per sample; Figure 29 [see next page], bottom) was prepared from 14 distinct tyrosine-derived diphenols and eight aliphatic diacids [287]. Up to 32 polymers were synthesized in parallel under identical reaction conditions, and conventional methods were used to characterize the polymers providing structure – property correlations.

In a different approach, polymerization reactions between different combinations of two starting materials have been found to lead to uniquely responding sensors with responses not

simply related to the proportions of the starting materials [288].

Figure 29. Library of polyarylates derived from diphenols and diacids

Radical polymerizations have been the focus of a variety of combinatorial approaches. Janda et al. applied a sequence of normal and living free-radical polymerizations to generate a library of 20 block copolymers possessing either block or graft architecture [289]. The members of the block copolymer library were then screened for their ability to serve as a soluble polymer support for organic reactions. One block copolymer could be identified that has a solubility profile that is complementary to the current soluble polymer of choice in liquid-phase organic synthesis (LPOS), namely polyethylene glycol (PEG).

Hawker et al. used combinatorial methods to identify novel nitroxide-based mediators for living free-radical polymerizations [290, 291]. Since the structure of the nitroxide moiety plays an important role in the success of living free-radical polymerizations, a structurally diverse, α-hydrogen-bearing nitroxide library was prepared and screened for the ability to control the polymerization of a variety of functionalized monomers. One α-hydrido alkoyamine was identified as the most promising candidate to effect the living free-radical polymerizations of a wide variety of monomers, e.g., styrenes, acrylates, acrylamides, and acrylonitrile-based monomers.

Researchers at Symyx Technologies have focused on combining rapid synthesis and rapid characterization techniques with full automation to reap the maximum benefit of combinatorial chemistry in the area of polymer science [292, 293]. Utilizing the stanard microtiter plate format, a 96-well, glass-lined aluminum reactor was developed to conduct organic reactions above the boiling point of the reagents without loss of pressure. Two methods of rapid molecular mass determination, i.e., precipitation – redissolution chromatography (PRC) and rapid-fire light scattering (RFLS), were used to screen the resulting polystyrene samples.

Combinatorial approaches were also employed to produce π-conjugated polymers with novel electrical and/or photofuntional properties. The photoluminescence of π-conjugated polymer thin films makes them interesting materials for flat panel displays. Since film preparation parameters are numerous, combinatorial concepts have been successfully applied for the synthesis of π-conjugated polymer thin films [294]. A variety of π-conjugated polymer building blocks was used for this study (Figure 30). Combinatorial film preparation was achieved by using appropriate mask shapes and synchronizing the rotation of the substrate with the target exchange. Vacuum evaporation (VE) or pulsed laser deposition (PLD) was used to deposite films on silica and/or Si substrates.

Figure 30. π-Conjugated polymers utilized for the combinatorial fabrication of thin films: PPP: poly(*para*-phenylene), PMP: poly(*meta*-phenylene), PPy: poly(pyridine-2,5-diyl), PTh: poly(thiophene-2,5-diyl), PPh2BPV: poly(diphenylene biphenylene vinylene), Poly(PP-co-PM): poly (*para*-phenylene-co-*meta*-phenylene)

13. Summary and Outlook

Combinatorial approaches to discovery and optimization of catalysts and materials will inevitably become the paradigm for modern scientific research. Considerable headway has already been made in this direction, as can been seen from the tremendous breadth of applications and approaches discussed herein. A multitude of tools are now available using combinatorial technologies that appropriately accommodate the new tasks and requirements for accelerated preparation of new materials. A common underlying theme associated with these technologies is miniaturization, parallelization, and automation so that large numbers of samples can be synthesized and screened efficiently. Rapid serial and parallelized adaptations of conventional analytical techniques will become increasingly important in the assay of materials properties, as will the development and implementation of new and unconventional high-throughput screening tools. Software development and engineering support in the construction and design of synthesis and screening tools are as crucial as further advances in chemistry, even when appropriate tools or robots for synthesis and screening automation are commercially available. Finally, the combinatorial methodology generates data much faster than the conventional research employing "empirical" and "rational" approaches to materials discovery, and, inevitably, the proper data handling and storage should accompany the high-throughput synthesis and screening to maintain the integrity of research and development efforts. Full realization of the combinatorial methodology will require the integration of chemistry, physics, engineering, and informatics to greatly enhance the probability of finding a global reaction optimum of a catalyst for a targeted reaction or materials with desired properties. In the future, the scientist's intuition may be shifted, at least to some degree, towards optimally programming and setting up appropriate experiments and screens as well as for the analysis of the obtained data and materials. All these efforts will require an enormous initial investment in all of these areas.

1. Introduction

Mortars based on mineral binders like lime, cement, or gypsum have been used for more than 8000 years in the construction of buildings. These mortars have mainly been used for laying stones and bricks (masonry mortars) and for coating walls (rendering mortars). Until the 1950s cement-based mineral mortars were exclusively produced and applied by so-called job-site mixing technology. Job-site mixing means transportation of the individual raw materials to the job-site and their mixing on site in the appropriate ratio. Thus cement, the most common mineral binder, is mixed with fillers (sand) before water is added to create the wet mortar for application.

Similar to the way in which job-site-mixed concrete was substituted by the economically and ecologically more favorable ready-mix concrete, job-site mixing techology for masonry and rendering mortars was replaced by factory-mixed dry mortars, also called dry-mix mortars. Dry-mix mortars or dry mortars are produced in specially designed dry-mix mortar plants in which mineral binder(s) and aggregates (sand) are mixed together in the appropriate way. This factory-based process also allows different additives and admixes to be added to these dry mortars to improve significantly their technical performance. Based on this technology individual dry mortars for specific applications can be produced according to formulations developed and pretested in the laboratory.

The factory-mixed dry mortars are delivered to the construction site in bags or in special silos and need only be mixed with water prior to use. Together with the appropriate equipment for efficient transport, mixing with water, and machine application of the wet mortar, this dry-mix mortar technology led to a drastic improvement in productivity in the application of high-volume products like masonry and rendering mortars.

The possibility of adding specific dry additives or admixes in a well defined ratio to the dry mix during the production also led to the development of high-quality mineral mortars with well-defined and specific technical properties. These highly specialized mortars corresponding to the requirements of the modern building industry can not be produced with job-site

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.f16_f01

mortar technology. Consequently, high-quality, additive- and admix-modified mineral mortars are today widely used in the building industry and have largely substituted other building materials such as ready-to-use paste compounds and liquid admixes used in combination with mineral mortars.

2. Development

2.1. Historical and Technical Development

For thousands of years the architecture and construction of buildings were closely associated with the use of mineral mortars. Lime plasters have been known for more than 8000 years, and gypsum mortars were used by the Babylonians about 6000 years ago. Hydraulic-setting mortars based on pozzolans (powdered volcanic ash) have probably been known for over 3000 years and were used in large amounts by the ancient Phoenicians, Greeks, and Romans.

In antiquity and the Middle Ages, additives and admixes such as soaps, resins, proteins, and ash were already mixed on the job site with mineral binders and aggregates to improve the technical performance of the resulting mortars.

Although a first patent on the manufacture and application of dry-mix mortars was published as early as 1893 in Europe, mortars were applied up to the 1950s exclusively as job-site-mixed mortars. For these mortars, the mineral binders (mostly cement) and aggregates (mostly quartz sand) are transported separately to the job site and are then mixed together by hand in the appropriate ratio. After mixing with water, the wet mortar is ready for application.

During the 1950s and 1960s in Western Europe and in the USA, but especially in Germany, there was a fast-growing demand in the construction industry for new building materials and technologies. The reasons for this included shortage of skilled workmen, the need for shorter construction times together with cost reduction, increasing labor costs, the diversification of building materials suitable for specific applications, new materials, and an increased demand for better quality of construction.

Job-site mortar technology was and is not able to adequately meet all these requirements. As a practical consequence the development of the modern construction and building chemical industry in the countries of the Western world from the 1960s onwards was influenced mainly by three important trends, which can be seen nowadays worldwide:

- Replacement of the job-site-mixed mortars by premixed and prepacked dry-mix mortars.
- Mechanization of mortar application, including bulk transportation systems (e.g., silos), mechanical systems for automatic mixing of dry-mix mortar with water, and machine application (spraying) of wet mortar.
- Modification of mortars with polymer binders (redispersible powders) and special additives (e.g., cellulose ethers) and admixes to improve product quality and to meet the requirements of the modern building industry.

The introduction of dry-mix mortar techology and the use of silo transport and machine appliation of mortars made it possible that from 1960 to 1995 the volume of render and plaster mortar application in Germany increased by 600 %, while the number of employees in this sector decreased by 25 %, that means, productivity increased by 800 % [1].

2.2. Advantages of Dry-Mix Mortars

In job-site mixing technology, for each building application a specific ratio of cement and fillers is mixed appropriately before being gauged with water, and the wet mortar is applied. The quality of such a mortar depends on the quality of the raw materials, their correct mixing ratio, the homogeneity of the mixture, and the consistency of the fresh mortar. Under these conditions the quality of mortars produced by job-site mix technology can not be guaranteed. The main disadvantages of job-site-mixed mortars are that the whole process can not be automated, and the producer and applicator of a job-site-mixed mortar can not give a warranty to customers and end users due to a high risk of inconsistent quality of the prepared mortars. In addition, additives can either not be added or can only be added with a high risk of dosage and mixing errors and of obtaining inhomogeneous mixtures. The possibilities for producing specialized and individual

products with job-site technology are very limited. Last but not least, handling and the logistics of job-site-mixed mortars are more complicated, and their applications are very limited.

In contrast to construction-site mortars, the modern dry-mix mortars are produced in a dry-mix mortar plant by mixing together all necessary ingredients such as binders, aggregates, and chemical additives. In this way different kinds of dry-mix mortars with well-defined product characteristics that correspond to the requirements for specific applications can be produced. The use of premixed and prepacked dry-mix mortars not only increases significantly production performance and the productivity on construction sites, but also guarantees a high degree of application safety and reliability in avoiding on-site mixing errors. Prepacked dry-mix mortars produced in a dry-mix plant assure that binders, aggregates, and additives of high and constant quality are mixed exactly in the same ratio, thus ensuring a consistent high level of quality [2], [3].

The raw materials used for the production of prepacked dry-mix mortars can be classified as follows:

1) Mineral binders
   a) Portland cement (OPC)
   b) High-alumina cement (HAC)
   c) Special cements
   d) Hydrated lime
   e) Gypsum
   f) Anhydrite
2) Polymer binder (redispersible powder)
3) Aggregates, fillers
   a) Silica sands
   b) Limestone sand
   c) Dolomite sand
   d) Marble sand
   e) Lightweight fillers
   f) Special and functional fillers
4) Additives
   a) Cellulose ethers
   b) Pigments
   c) Defoaming agents
   d) Air-entraining agents
   e) Retarding agents
   f) Accelerators
   g) Thickening agents
   h) Hydrophobing agents
   i) Plasticizing agents
   j) Superplasticizer

The main applications of dry-mix mortars can be classified as in the following:

1) High-volume products (ca. 70 % of total dry-mix mortar volume produced)
   – Masonry mortars
   – Base renders (cement- and gypsum-based)
   – Bricklaying mortars
   – Bricklaying adhesives
   – Cement-based screeds
   – Gypsum-based screeds
   – Dry concrete
   – Shotcrete concrete
   – Mineral plasters
2) Specialized products (ca. 30 % of total dry-mix mortar volume produced)
   – Ceramic-tile adhesives
   – Building adhesives
   – Tile grouts
   – Grouts
   – Decorative mineral plasters
   – Powder paints
   – External thermal composite insulation systems
   – Trowelling compounds
   – Flooring compounds
   – Repair mortars

The two different approaches to produce fresh, wet mortars ready for application either as a job-site mixed mortar (process A) or as a factory-made prepacked dry-mix mortar (process B) have major consequences for handling and productivity, as exemplified for base-render application in Table 1.

The application of high-volume dry-mix mortar was strongly promoted by the development of bulk transportation containers (silo systems) and mechanical systems for gauging the mortars with water and pumping for mechanical application by spraying. Compared to the manual gauging of dry-mix mortars delivered in bags to the job site (process B), the use of automatic gauging and pumping devices for the mechanical application of the mortar leads to an additional improvement in productivity (process D).

Table 1. Comparison of production, transport, and application of job-site-mixed mortars and dry-mix mortars

Process∗	A	B	C	D
Transport of sand and cement separately to the job-site	+			
Manual mixing of the mineral binder and the aggregates on the job site	+			
Transport of the prepacked dry-mix mortar in bags to the job site		+	+	
Transport of the prepacked dry-mix mortar in silos to the job site				+
Manual mixing of the mortar with water	+	+		
Manual application of the wet mortar	+	+		
Machine mixing of the dry-mix mortar with water and machine spray application			+	+
Productivity (m^2 per man shift) for a render application	10	25	40	50 – 60

∗ A: completely manual method (job-site mixing technique); B, C, D: dry-mix mortar production in a dry-mix plant with different methods of transport and application.

The handling of dry-mix mortars in bags could be eliminated for many high-consumption applications by filling the dry-mix mortars produced in the dry-mix plant into containers 1 – 20 m^3 in volume which are transported to the site. With appropriate conveying systems the dry mortar is transferred directly from the silo into the attached mixing and pumping unit, where it is gauged automatically with water and pumped for spraying.

Combining the transportation of the dry-mix mortar in silos or containers with automatic gauging, pumping, and mechanical application of the mortar provides a further improvement in productivity (process D). In addition to the improved productivity, the automatic mechanical gauging and spraying of dry-mix mortars ensures consistency in handling and application of these products. Possible errors such as over- or underdosage of water or incorrect composition of the mortars are eliminated, which is especially important if less experienced or unskilled workers are working on the job site.

In Western Europe the consequences of this development were phenomenal. Since the 1960s a huge number of modern dry mortar plants have been established with millions of tonnes of capacity. In Germany, for example, nowadays approximately 100 dry mortar plants exist, producing 10×10^6 t/a of dry-mix mortars. There was a tremendous boom in dry-mix mortar technology after reunification of Germany after 1990, which now continues in the countries of Eastern Europe. The average growth rate for dry-mix mortar applications in Europe is approximately 12 % per annum, based on a production of about $35 – 40 \times 10^6$ t/a in 2000 [4].

3. Composition

Dry mortars are generally composed at least of three components: a binder, an aggregate, and additives.

Modern dry mortars are composed of many more components than those which were mixed directly on the site in the past. Today the simplest formulations are masonry mortars, brick-laying mortars, and low-quality tile adhesives, while highly sophisticated and high-performance dry mortars like self-leveling floor underlayments and decorative plasters may contain up to 20 ingredients. In this article the word aggregates is used for all types of mineral ingredients which do not have a binder function, even if they are added in small amounts like mineral ingredients with special functions, e.g., functional fibers or pigments. Other ingredients with small addition rates (redispersible powders) are treated as organic binders, although many others describe them as additives. The effect of using redispersible powders, especially in tile adhesives, shows clearly that they have a binder function. On the other hand, methyl cellulose, a multipurpose additive, is described in the chapter on additives although it also has a certain binder effect. In this case the binder effect does not play the major role.

3.1. Binders

The binder glues aggregates and other particles together and provides adhesion to the substrate. Due to their physical or chemical reaction binders play the major role for the final strength of the mortar. Binders can be classified as hydraulic and nonhydraulic binders. The former also set under water.

The setting reaction of the binders cement and hydrate lime occurs by chemical reaction. Cement reacts on contact with water during mixing while hydrate lime (without hydraulic portions) sets by reaction with atmospheric carbon dioxide. Gypsum and organic binders set physically: gypsum by recrystallization with water and formation of matted crystal needles, and organic binders by forming a homogeneous polymer film.

3.1.1. Mineral Binders

Cement (see also → Cement and Concrete). In dry mortars ordinary portland cement (OPC) is mainly used. The hydration reaction leads primarily to the formation of calcium silicate hydrates, which retain their strength and stability even under water (hydraulic binder). While the quality of an OPC like CEM I 32.5R (for nomenclature, see DIN 1164 [5]) is sufficient for bricklaying mortars, masonry cement, renders, and many plasters, in tile adhesives higher qualities like CEM I 42.5R or CEM I 52.5R are desired. Dry mortars that are both mortars and decorative finishes, such as decorative plasters and tile grouts, mostly contain white portland cement. Fast-setting high-alumina cement (e.g., Fondue Lafarge) consists mainly of calcium aluminates and is used for dry mortars that require fast-setting properties or high-temperature stability.

Gypsum [6] (see also → Calcium Sulfate). Calcium sulfate hemihydrate and anhydrite both set with water by forming calcium sulfate dihydrate.

Calcium sulfate hemihydrate exists in two crystalline forms (depending on the production process): the α-form with larger crystals, higher tensile and compressive strength, and lower water demand, and the more amorphous β-form with high porosity and lower tensile and compressive strength and an up to three times higher water demand.

Anhydrite exists in two application-relevant phases: the anhydrite II phase, which is of importance in anhydrite-based screeds and the anhydrite III phase, which is a part of the multiphase gypsum used for plasters. Gypsum plasters contain β-hemihydrate as well as anhydrite II and III. Gypsum-based joint filler contains β-semihydrate.

Hydrated Lime (see also → Lime and Limestone), [7]. Hydrated lime sets by reaction with carbon dioxide to form calcium carbonate and is therefore not a hydraulic binder. Hydraulic properties in some hydrated lime result from impurities or added materials with pozzolanic properties. For centuries hydrated lime was by far the most important binder in mortars. Today it is largely substituted by hydraulic binders, which set faster, but it is still in use, mainly because of its plastic properties. The workability of many dry mortars is improved by adding 5 – 30 wt % hydrated lime to the cement. Limes (including powdered hydrated lime) for building purposes are specified in DIN EN 459 [8].

3.1.2. Organic Binders

Improving the characteristics of a cementitious mortar with organic materials is well known. In antiquity, for example, proteins in the form of liquid milk or even blood were used. In most modern applications, mortars unmodified by organic polymer binders are no longer able to meet state-of-the art technical requirements. Even cementitious mortars that contain cellulose ethers as an additive to improve their water-retention capability and workability characteristics adhere poorly, or not at all, to many of the materials used in the modern construction industry (e.g., polystyrene, cement fiber and wood panel; non-absorbent substrates like old tiles and fully vitrified tiles). Furthermore, cementitious mortars are very hard, brittle, and inflexible materials, but for many applications flexible and deformable cementitious mortars must be used. Thus, for many applications in the modern construction industry the modification of cementitious mortars with polymers today is a must. In two-binder systems, the mineral binder cement and the polymer binder in the form of a redispersible powder complement each other ideally. Their combination results in outstanding synergistic properties and characteristics of the dry-mix mortar which cannot be produced by either of the two individual binders alone.

In the early 1930s water-based liquid dispersions [9] were added prior to or together with the gauging water if required. Mortars which are modified in this way are referred to as two-pack systems (powder-form mineral binder plus liquid polymer binder in a second pack). However, in practice many faults occurred with the use of the two-pack (or two-component) systems at the construction site. The main difficulty is the precise dosing of the polymer dispersion in its liquid form.

Dosing errors may occur due to insufficient knowledge, experience, and training of workers concerning the appropriate dosage for a specific application with precise requirements, or due to incorrect dosage, which may happen unintentionally by error or even intentionally to save on short-term costs. Incorrect dosage of the liquid polymer dispersion will change the characteristics and the technical performance of the mortar significantly, and this will lead to severe damages in various construction materials, e.g., through insufficient adhesive bond strength, flexibility and/or durability. Other reasons that argue against two-pack systems, apart from the difficult and risky handling, are the additional expenses and logistics difficulties (e.g., the need for additional containers and their subsequent disposal, storage and transport of liquid dispersions which could freeze or deteriorate by microbiological attack, more time consuming and ponderous handling on the job site with the two-pack system).

The invention of redispersible powders (trade name Vinnapas® Redispersible Powder) by Wacker Chemie in 1953 made possible the production of the first polymer-modified dry-mix mortars, known today as one-pack or one-component systems. Redispersible powders are polymer binding agents produced by spray-drying special water-based dispersions, mostly based on vinyl acetate – ethylene copolymers. These are often also referred to as redispersible powders [10], [11], because after mixing or redispersion with water, these powder polymer binders can be returned to their original water-based dispersion with all their typical characteristics and functions as polymer binders. The polymer film acting as a binder is formed after partial evaporation of the water by coalescence of the individual polymer particles. This polymer film acts as an organic binder, gluing together the filler particles, reinforcing the mortar structure and providing an excellent adhesion at the mortar – substrate interface. Polymer films in a cement mortar are shown in Figure 1.

The use of factory-made dry-mix mortars with precisely stipulated proportions for cement, aggregates, additives, and redispersible powders as organic binder results in a high-quality product with a high degree of application safety by avoiding possible errors during dosing and mixing at the construction site.

The modification of dry-mix mortars with redispersible polymer powders improves, depending on the dosage, the adhesive bond strength on all kind of substrates, the flexibility and deformability of the mortars, the flexural strength, and the abrasion resistance, the toughness, the cohesion and the density (impermeability) of the mortar as well as the water retentivity and the workability characteristics. In addition special redispersible powders with a hydrophobing effect can result in a strong water-repellent effect of the mortars.

3.2. Aggregates

The majority of aggregates are normal size fractions of quartz, limestone, or dolomite. To adjust the grain-size distribution (see Section 5) normally different granulometric fractions of aggregates are necessary. Additionally decorative fractions of special granulometries like calcite, marble, jurassic limestone, or mica are used, mainly for decorative plasters. To reduce the density of a dry mortar and to increase the insulation effect lightweight aggregates like perlite, vermiculite, glass foam, expanded clay, and pumice are used as additional aggregates. Because of their low density (typically 80 – 500 kg/m^3) only few per cent by weight is added to the mix. Dry mortars for decorative renders or tile grouts are often colored with pigments.

3.3. Additives

Without additives modern dry mortars would not exist and many technical properties could not be achieved. Relative to the mineral ingredients the content of additives typically lies between 0.1

Figure 1. Scanning electron micrograph (× 1500; Wacker Polymer Systems) of the interface between a polymer-modified ceramic-tile adhesive (left) on a porcelain tile (right). The polymer films at the interface between the surface of the porcelain tile and the cementitious mortar can be seen clearly.

and 10 wt %. The additives are of organic or inorganic origin, often of polymeric nature. They can improve the mixing of the dry mortar with water, the properties of the wet mortar such as rheological behavior or the workability as well as the properties of the set mortar including the setting behavior.

3.3.1. Cellulose Ethers [12]

Cellulose ethers are used as thickening and water retaining agents in dry mortars. Cellulose ethers are of major importance as additives, even though their addition rate is very low (normally 0.02 – 0.7 %). Out of all additives cellulose ethers together with redispersible powders cause the largest range of effects in dry mortars. The mainly used cellulose ethers in dry mortars are methyl hydroxyethyl cellulose (MHEC) and methyl hydroxypropyl cellulose (MHPC). Together they have a market share in dry mortars of at least 90 %. Colloquially they are still called "methyl cellulose" or "MC", although pure methyl cellulose today has a very small market share. Other technically relevant cellulose ethers with a small share in the dry-mortar market are ethyl hydroxyethyl cellulose (EHEC) and hydroxyethyl cellulose (HEC). As (sodium) carboxymethyl cellulose is not stable in the presence of calcium ions, it is used only in few applications as a thickener.

The following sections cover relevant properties of MHEC and MHPC. As these properties are valid for both products, here they are simply referred to as MC.

Formation of Solutions and Wet Mortar Mixes; Viscosity Buildup. MC is water-soluble on a large temperature range. The most suitable MC's for dry mixes are powders whereby 20 – 60 wt % of the particles have a size smaller than 63 μm. The dry mix, in which MC particles are dispersed between binder and aggregate particles, avoids the formation of lumps which occurs only if powders are poured directly into water. Coarse MC products, normally classified as granular materials, are easy to dissolve in water without lump formation, but their slow dissolution makes them unfavorable for dry mortar mixes. For dry mortars with a neutral pH it should be considered that the granulometry is not the only parameter deciding the solution behavior of the MC. Some MC-grades are covered with a chemical crosslinking agent ("retarded solubility"), which causes particles to dissolve quickly only under alkaline conditions (e.g., coming from cement or hydrated lime). The alkalinity leads to an immediate breakdown of the crosslinking as well as to a fast dissolution

of the MC in the mortar. Originally MC grades with retarded solubility were not developed for dry mortar, however, they have eventuelly spread to the dry mortar market.

In pure solution and in a wet mortar, MC builds up a certain viscosity. The differences between low and high viscosities can be seen easily in a 2 % aqueous solution. Many MCs are specified by their viscosity measured at this concentration. The viscosities of such solutions varies between aqueous (viscosity up to a few hundred millipascals) up to jellylike (viscosity of several thousand millipascals). Different MC producers use different methods and apparatus to specify the viscosity of their MCs: the Haake Rotovisko, Höppler, Ubbelohde, and Brookfield methods are mainly in use. The results of viscosity measurements on the same sample can differ by up to several hundred per cent between two methods, and this should be borne in mind when comparing viscosities of MCs from different producers.

Stickiness and Workability. Stickiness is an expression mainly used in the leveling of plasters and renders. Here "stickiness" means the feeling of adhesion that the worker experiences to be between the leveling tool and the wall. High stickiness requires more force during leveling and results in a lower workability. Both properties can be influenced by the MC.

Water Retention. The water retention value (WRV) of a mineral plaster is the percentage of water that remains in the plaster after capillary dewatering by an absorbant substrate (DIN 18555, part 7) [13].

Cement- and gypsum-based mortars need water for setting, and this water must be retained in the mortar for a longer period of time. The thickness of thick-bed mortars widely used in the past (normally in the range of centimeters) protected the mortars from drying out too fast after coming into contact with water absorbing substrates, the sun, or other environmental conditions like wind, dry air, or a high ambient temperature. Today, wall materials with high capillary forces are used (e.g., aveated light weight concrete), and the thickness of mortar layers generally has decreased. MC is necessary to retain the water during the setting reaction. The high water retention of a modern dry mortar is mainly due to MC. Figures 2 and 3 show an example of the water retention of a wet mortar as a function of concentration and viscosity, respectively, of the added MC.

For the measurement of water retention see Section 5.

Water Demand and Yield. A mortar requires a certain consistency which is well known to skilled workers. They add as much water as is necessary to get the right consistency. The water demand depends on the ingredients and their addition rate in the formulation. MC is the main factor which influences the water demand. Mainly the viscosity, the addition rate, and the additional thickening effect of MC are the parameters. The water demand (water-solid-factor) influences also the yield of a mortar. It is measured in liters of wet mortar per 100 kg of dry mortar and is an important parameter for the efficiency of lightweight plasters. Some MC producers supply special MCs which garantees high yields in the mortar. This can help to reduce the amount of lightweight aggregates.

Other properties which can be influenced with MCs are open time and tensile adhesion strength of a tile adhesive as well as the slip resistance of a tile in the mortar (see Section 5), the rheological properties, plastification, and lubrication.

3.3.2. Other Additives

Starch Ethers. Mainly hydroxypropyl starches are added to plasters. Despite their low viscosities (mainly 100 – 500 mPa s in 2 % solution) they distinctly increase the viscosity of mortars when added to MC-containing mortars. Typical addition rates are between 0.01 and 0.04 % in cement-based renders and plasters, and 0.02 – 0.06 % in gypsum-based plasters. The water demand of the plaster is slightly increased, and this is associated with a slightly higher yield. The water retention of the mortar is not increased. With regard to the workability the sagging of the wet mortar from vertical walls and supports is reduced. At the optimum dosage the workabilities are improved.

Air-entraining agents act physically by entraining air micropores in the mortar. This leads

Figure 2. Water retention of a wet mortar as a function of the concentration of the added methyl cellulose (Walocel MKX 30 000 PP 01, Wolff Cellulosics, viscosity 30 000 mPa s, measured with a Haake Rotovisko)

Figure 3. Water retention of a wet mortar as a function of the viscosity of methyl cellulose (2 % solution, 20 °C, shear rate: $D = 2.5\ s^{-1}$, measured with a Haake Rotovisko)

to a decreased wet mortar density, a better workability, and a higher wet mortar yield. The included air leads to better insulation against cold and heat, but also to lower strength. Air-entraining agents are based on powder form and mainly sodium salts of fatty acid sulfonates and sulfates. The addition rates in plasters and masonry mortars normally varies from 0.01 to 0.06 %. The optimum addition rates can be found by monitoring the air content of the mortar and its workability.

Accelerators. Accelerating systems are used in large amounts in cement-based systems to adjust the desired setting properties. In particular calcium formate (e.g., Mebofix®, Bayer, Leverkusen, Germany) or lithium carbonate (e.g., from Chemetall, Frankfurt, Germany) are used successfully. The addition rate is up to 0.7 % for calcium formate, and up to 0.2 % for lithium carbonate.

Retarders. The main application for retarders are gypsum plasters and gypsum-based joint fillers. Without retardation the setting of gypsum is too fast. Different retarders are used, mainly salts of fruit acids like tartaric or citric acid and of synthetic acids (e.g., Retardan® grades, from Tricosal, Illertissen, Germany). The typical dosage lies between 0.05 and 0.25 %.

Hydrophobic agents (water-repellent agents) prevent water from penetrating into the mortar, but the mortar remains still open for water vapor diffusion. The performance of hydrophobic agents can be measured by the capillary water absorption (DIN 52617) [14].

The main applications for hydrophobic agents are cement-based plasters for exterior application, mineral waterproofing slurries and tile grout. There are two groups of hydrophobic agents on the market: metal salts of fatty acids. (e.g., zinc stearate or sodium oleate, e.g., from Greven Fettchemie, Bad Münstereifel, Germany), and polymeric redispersible powders with hydrophobic properties (some Vinnapas® grades, Wacker Polymer Systems, Burghausen, Germany). The first group has the advantage of lower addition rate (0.1 – 1 %), the second one the advantage of significantly better durability, because hydrophobic redispersible powders are not washed out of the plaster by rain even after years. Additionally, the use of hydrophobic redispersible powders does not lead to wetting problems during mixing the dry mortar with water and it improves the adhesion of the cured mortar to the substrate (see Section 3.1.2).

Superplasticisers have a strong influence on the water demand of a mortar. A mortar containing superplasticisers requires less water than usual to get the same consitency. Consequently, an unchanged water demand leads to a lowering of the consistency. The effect of superplastification is explained by the model [15] that different surface charges of the cement particles lead to the inclusion of water when they agglomerate. By the adsorption of the superplasticiser the surfaces are discharged and water is set free. Depending on legal restrictions and technical advantages casein (many producers) or synthetic superplasticizers are used, e.g., on the basis of sulfonates of lignin, naphthalene, melamine – formaldehyde condensates, or polyether carboxylates. Examples of producers are SKW (Trostberg, Germany), Sika (Switzerland), and Perstorp (Sweden). Superplastizisers are mainly used in mortars which need very good self-leveling properties like self-leveling floor underlayments, screeds, and pourable flooring tile adhesives. The dosage normally lies in the range of 0.2 – 1 %.

Fibers can be distinguished into two groups: long fibers are mainly used for reinforcement of mortars. Short fibers (e.g., Arbocel and Lignocel grades from J. Rettenmaier & Söhne, Ellwangen-Holzmühle, Germany) are used in influence wet-mortar properties and water demand.

Defoamers reduce the air content in wet mortars (e.g., Agitan P products from Münzing Chemie, Heilbronn, Germany). Powder defoamers on a different chemical basis (mainly hydrocarbons, polyglycols or polysiloxanes on an inorganic carrier) are in use.

4. Production

Production, storage, transport, and quality control of dry-mix mortars are defined in DIN 18557 [16].

Modern dry-mix plants (Fig. 4) with a production capacity of typically 40 000 to 250 000 t/a mostly are built on a small area because the production line is oriented vertically, and the silos for the raw materials are placed above the mixing unit.

After appropriate quality control, the raw materials are transported by the receiving system to the different silos at the top of the plant. Consequently, the material flow is mainly gravitational, which saves on investment and running costs. The raw materials are transferred by gravity or by appropriate conveying systems (disk feeders, dosing screws, pneumatically) into the high-accuracy hopper-scales weighing system. Controlled by the fully automated electronic control system, the mixing unit is filled with all raw materials needed for each formulation for a specific dry-mix mortar. As mixing unit mostly special mixers are used which are suitable for the whole product range of dry-mix mortars (from fine-particle materials up to coarse dry mortars). Such mixing units, available in a wide variety of different sizes and designs, allow short batch cycle times and fast, homogeneous mixing. The temperature of the dry-mix materials should not exceed 50 °C during the whole mixing process to avoid deteriorating the thermoplastic and sensitive additives. After a short mixing process of about 3 – 10 min for highly efficient modern mixing units, the homogeneous dry-mix mortar is discharged into the intermediate finished-product storage silo. After quality control, the dry-mix mortar is discharged into transport silos or transferred to bagging and palletizing units, ready for the transport to the con-

Figure 4. Schematic diagram of a dry-mix mortar plant (m-tec, Neuenburg, Germany)

struction site. Figure 5 shows a typical dry-mix mortar plant.

In the production of dry-mix mortars, the quality of all raw materials used, especially the bulk mineral materials, must be controlled according to the national standards (e.g., EN 196 for cements). If aggregates like silica quartz sands are not available in the appropriate quality, the dry-mix mortar plant must include installations for grinding, washing, drying, and classification into different sieve fractions. The residual humidity of all fillers should not be higher than 0.3 %, and the temperature of the sand after the drying process should not exceed 60 °C before being used. The sieve curve within the different filler fractions should be constant without large variations (e.g., by combining several subfractions).

The design, the size and the number of silos for all raw materials and the design of the whole mixing and packaging unit depends on the raw materials available and the number, types, and volume of different dry-mix mortars to be produced in the dry-mix mortar plant. For all gypsum-based products usually a separate production line is used to avoid contact or mixing of cement-based products with gypsum.

5. Testing

Consistency. Applying a mortar to a support requires to mix it with a certain amount of water. Skilled building workers instinctively mix the dry mortar with the amount of water which leads to the desired application consistency. A higher or lower amount of water leads to undesired properties. The required amount of water for mixing is described by the term w/s (water to solid ratio).

Figure 5. Typical dry-mix mortar plant (m-tec, Neuenburg, Germany)

During the development of a dry mortar the w/s values should be adjusted to a consistency which will probably be used also on building sites. If formulations with different addition rates of additives or different additives are compared, it is generally worthless to compare formulations with the same w/s, because nearly all additives change the consistency or the w/s slightly. To find a way of controlling the consistency and to compare different formulations, several testing procedures exist. The consistency of mortars, renders, and plasters is checked by the slump method, which is done in a similar way as in the concrete industry (→ Cement and Concrete, Chap. 2.4.1.). The standards DIN 1168, part 2 (only for gypsum-based products) [17], DIN EN 13279, part 2 [18], and DIN 18555, part 2 (for mortars with mineral binders) [13], define the slump to be "the diameter in millimeters of a pat made of a mixture of water and building plaster and formed by vertical blows after removal from the mold and jolting of the mixture" [13]. The consistency of more liquid products like self-leveling floor screeds or pourable flooring tile adhesive can be determined by the diameter of flow. This procedure does not require jolting. The consistency of a tile adhesive can be controlled by viscosity.

Water Retention. The standard DIN 18555, part 7 [13] describes the measurement of water retention. The water-absorbing wall is simulated by water-absorbing filter plates. The test is carried out on a plaster with a consistency as used in practice. The wet mortar is spread onto filter plates. After a certain time the water amount absorbed by the filter plates is weighed. Than the water retention is calculated in %. Different kinds of mortars require different water-retention values for good application properties.

Setting Time. The setting behavior of gypsum-based building plasters is determined by the Vicat needle test according to DIN EN 13279, part 2 and DIN 1168, part 2. [17], [18]: "The start of setting of building plasters containing additives is indicated by the time in minutes after which a Vicat needle, in the course of a penetration test into a plaster sample, comes to a standstill at a specified height." The time is calculated from the commencement of moistening of the building plaster with water. Coarser systems such as cement renders and plasters are less suitable for the Vicat testing procedure.

Air content. Freshly mixed mortars contain pores, one origin of them being air entraining agents, another being adsorbed air on the surface of the particles. DIN 18555 part 2 [13] describes a method to determine the total amount of air pores in a fresh mortar. It is an integral method which does not give any indication about the size or the distribution of the pores. "The air content of fresh mortar shall be measured by the pressure method using a preset test apparatus with a capacity of 1 dm^3. The test apparatus shall have a pressure chamber in which a defined pressure is produced. By opening an overflow valve a pressure balance is affected between the pressure chamber and the sample container (measuring vessel) which is filled with fresh mortar. The drop in pressure is a measure of the air content in the fresh mortar." [13]

Granulometric analysis mainly is done with screen sizing. The residues on the test sieves are weighed and expressed as a percentage of the initial weight. Plotting the diameter of the particles as a function of the percentage sieve passage gives the individual granulometric curve. The curve has a specific shape for each dry mortar. The coursness of dry mortars also varies (Fig. 6). The granulometric range of most dry mortars varies between 0.1 and 4 mm.

In some mortars a high wet mortar density is necessary to lead to high compressive strengths. In such cases the granulometric distribution of all mineral components should be optimized accordingly. To use a simple picture, the spaces between the bigger particles should be filled by smaller particles to give the best space filling. This best distribution of diameters of particles can be calculated and and plotted as a Fuller curve (Fig. 7).

Open Time. In the colloquial speech used on the building sites "open time" is a general expression for the length of time in which a freshly mixed mortar can be applied. The expression "open time" mainly is used for applying tile adhesives, sometimes also for plastering and rendering. A more precise definition of "open time" is given in the following three definitions: The former DIN 18156 (part 2) defines the "open time" to be the time between the application of the mortar layer and the formation of a skin. The skin formation can only be tested qualitatively with a wad of cotton. Another testing procedure defines the "open time" as the time after which the wetting of the back of the tile is at least 50 % of the square of the tile. Nowadays European laboratories are testing the open time mainly according to EN 1346 [19]. Here the open time (in minutes) is the largest time range after which the necessary tensile strength of a tile adhesive according to EN 12004 is reached. The tested times are 5, 10, 20, and 30 min.

Slip Resistance. A tile adhesive should have a good slip resistance mainly for the following two reasons: for tiling with heavy tiles like marble tiles, and second for countries where the tiling of a wall starts from the top (as in Germany) and not at the bottom. In the latter case the lower tile supports the upper tile and prevents it from slipping down.

The slip resistance is measured with a standard tile of size 10 × 10 cm and a weight of 200 g on a concrete slab according to EN 1308 [20].

Tensile adhesion strength is an important property of many dry mortars. For tile adhesives EN 1348 [21] specifies four conditions of storage: standard storage under standard climatic conditions for 28 d, after water immersion, after freeze – thaw cycle, and after heat aging storage.

6. Applications

6.1. Brick-Laying Mortars and Related Adhesives

Brick-laying mortars are used to join all kinds of bricks: red clay bricks with low water absorption, strongly absorbing sand-lime bricks, and aerated light weight concrete. Generally, bricks with low water retention applied in thick layers require mortars with low water retention, while smooth and even bricks with high water absorption require a mortar with high water retention applied in thin layers. Table 2 lists the different formulations.

DIN 18555, parts 1 – 9 [13] describes the testing of mortars with mineral binders. Most of them are valid for brick-laying mortars as well as for cement-based renders and gypsum plasters.

Table 2. Typical formulations of a brick-laying mortar and an aerated light weight concrete adhesive (in parts by weight)

Component	Brick-laying mortar	Aerated light weight concrete adhesive
Cement (e.g., CEM I 32.5R)	12 – 20	36
Hydrated lime	0 – 6	4
Limestone dust, 0 – 0.1 mm	10 – 20	
Quartz or limestone sand, 0 – 4 mm	60 – 80	
Quartz sand, 0 – 0.5 mm		60
Air-entraining agent	0.01 – 0.03	
Methyl cellulose, medium viscosity	0.02 – 0.04	
Methyl cellulose, high viscosity		0.3 – 0.4

6.2. Renders and Plasters

Plaster is defined in DIN 18550, part 1 as "a coating of plaster mortar or coating materials applied to walls and ceilings in one or more layers in a

Figure 6. Maximum grain size of some European mortars (mm)

Figure 7. Reference curves calculated from the Fuller equation

specified thickness, which does not acquire its final characteristics until it has set on the building component" [22]. Different types of dry mortar render and plaster are classified on the basis of the type of binder used:

- Plaster and render mortar with mineral binders (cement, gypsum, and possibly hydrated lime)
- Decorative plaster mortar with cement, redispersible powder, and possibly hydrated lime as the binder (see Section 5)

Dry mortar render and plaster with other binders like potassium silicate, redispersible powder as the sole binder, hydrated lime as the sole binder, and clay are not covered here. Plasters assume a range of physical tasks, for instance, protection against weathering or chemical or mechanical actions. Weathering means the ingress of moisture or fluctuations in temperature. In addition plasters have to confer adequate protection against driving rain, but they are used also for bathrooms and other rooms where moisture occurs. Cement or lime – cement plasters are used to satisfy these requirements.

Render and plaster must have good water vapor permeability and be suitable for painting and hanging heavy papers. Mineral renders, typically applied in a single layer with a thickness of ca. 10 – 30 mm, also serve as a uniform and smooth substrate or load-bearing layer for subsequent finishing coating materials like ceramic tiles, paints, and decorative finishing coatings. Cement-based renders are used for exterior applications and wet rooms, whereas gypsum-based renders are used exclusively for interior walls.

Nowadays, in most European countries (not in the UK) machine-applied render/plaster is much more common than manually applied render or plaster. Accordingly, the render/plaster for machine application must fulfill the additional requirements of a very rapid development of consistency and high water retention. Both parameters are steered by choosing the appropriate grade of methyl cellulose. Next to the trend to machine application, there is a tendency to use more lightweight plasters.

Cement and Lime – Cement Renders. The main requirements for cement and lime – cement renders are high non-sag properties during application, easy workability, low stickiness to the leveling tool, and crack-free setting. To fullfill these requirements, the formulation requires the optimum concerning granulometry and the addition of additives like methyl cellulose, starch ethers, and air-entraining agents. Table 3 lists typical formulations of a lime cement render and of a lightweight render based on cement.

Table 3. Typical formulations of a standard lime – cement render and a lightweight cement render (in parts by weight)

Component	Lime – cement render	Lightweight cement render
Portland cement CEM I 32.5R	8 – 12	18 – 25
Hydrated lime	6 – 8	0 – 5
Quartz sand, 0.2 – 0.8 mm	80 – 85	
Limestone sand		60 – 75
Limestone dust		5 – 7
Expanded polystyrene		1 – 2
Starch ether		0.01 – 0.02
Hydrophobic agent	0.15 – 0.25	0.1 – 0.2
Air-entraining agent	0.015 – 0.03	0.03 – 0.05
Methyl cellulose, viscosity 15 000 mPa s	0.08 – 0.12	0.1 – 0.12

Lightweight renders for thermal insulation are specified in DIN 18550, parts 3 and 4 [22].

Gypsum Plasters (→ Calcium Sulfate). As the working steps necessary for a gypsum plaster are more complicated and time-consuming than for a cement render, the typical formulations are also more complicated. The main focus is always on the correct adjustment of the setting retardation, which enables the worker to finish all steps of the work before the surface sets or becomes dry. As the working traditions are different in many countries, the local formulations always have to be adjusted to the different working procedures. A main difference in working concerns the final working steps after the second leveling. In central Europe the surface is wetted with water and a cream is rubbed out of the surface with a sponge, followed by the smoothening with a knife, which results in extremely smooth surfaces. In southern Europe and Great Britain, watering of the surface is avoided, and this leads to a coarser surface. To obtain the desired smoothness, the surface is plastered with a fine-grained top coat.

Lightweight gypsum plasters containing perlite or vermiculite are very common. Especially in these formulations methyl cellulose plays an important role in increasing the yield and saving on the cost of the lightweight aggregates. In a lightweight gypsum plaster for machine application the right MC allows 100 – 200 L of perlite to be saved per tonne of plaster for the same coverage compared to a MC without any additional thickening effect. Such an MC will yield to an approximately 10 % higher coverage of the plaster mortar.

The true yield of a machine-applied lightweight plaster can be measured only in a plaster spaying trial. Typical German gypsum plasters have yields in the range of 80 L/100 kg of dry mortar for a gypsum – lime plaster, and up to 120 L/ 100 kg of dry mortar for machine-applied gypsum lightweight plaster.

Relevant standards are draft DIN EN 13279, parts 1 and 2 [18] (formerly DIN 1168, parts 1 and 2).

Table 4 shows typical formulations of a gypsum plaster, a gypsum – lime plaster, and a lightweight gypsum plaster.

Textured Mineral Finishing Plasters. Mineral finishing plasters, stuccos, putties, and skim coats are part of a coating system and are applied usually on a thick-layer base coat (render) or on other types of uniform and smooth surfaces (concrete, plasterboard, etc.). For exterior walls, mainly lime – cement plasters are used as a decorative finishing material. Finishing plasters must provide the facade with an optically attractive surface finish and have to fulfill physical functions such as a durable protection of the covered wall areas and undercoats against dampness and weathering.

Table 4. Typical formulations of a gypsum plaster, a gypsum – lime plaster, and a lightweight gypsum plaster (in parts per weight)

Component	Gypsum plaster	Gypsum – lime plaster	Gypsum lightweight plaster
Gypsum	74 – 98	40 – 50	70 – 100
Limestone		20 – 35	
Hydrated lime	1.5 – 5	15 – 20	2 – 5
Perlite		0.3 – 0.8	3 – 5
Starch ether	0.01 – 0.04	0.01 – 0.03	0.01 – 0.05
Air-entraining agent	0.015 – 0.03	0.015 – 0.03	0.01 – 0.03
Setting retarder	0.025 – 0.05	0.025 – 0.04	0.025 – 0.04
Methyl cellulose, viscosity 30 000 mPa s	0.16 – 0.23	0.16 – 0.23	
Methyl cellulose for high yield			0.2 – 0.24

To meet their required physical functions over long periods, mineral finishing coating materials for exterior application must have a good adhesion to the substrate, a low water absorption and a high water-repellent effect (low coefficient of water-absorption), good drying characteristics (good water-vapor permeability), and low susceptibility to cracking; the modulus of elasticity of the mineral coating should be lower than the modulus of elasticity of the layers below it.

These requirements are met in an exemplary manner by mineral-textured finishing plasters produced as factory made dry-mix mortars. The term "finishing plaster" nowadays refers to facade-coating materials pigmented in white or light pastel colors which are used as the final surface finish without any additional painting being necessary. Mineral finishing plasters are composed of hydrated lime and cement as mineral binders, aggregates (fillers), pigments, and additives such as cellulose ethers and starch ethers to improve the water retention and processing. If required, other additives such as air entrainers, water-repellent agents, retarders, and fibers are added. The ratio of cement and hydrated lime can be varied according to the different requirements; the higher the cement content the higher the compressive strength, the toughness, and the water resistance, but there is also a higher risk of crack formation due to the brittleness and shrinkage of the mortar. The higher the content of hydrated lime, the better the workability, and the lower the compressive strength. Carbonate fillers such as marble or limestone can be used additionally or even exclusively instead of silica sands. The technical performance of the finishing plaster can be improved significantly by the addition of organic polymer binders in the form of redispersible powders. The different structures of the hardened mortar originate from a different particle size distribution of the fillers used in the formulation (structure-giving large grains) and from the application method (application by spraying, brush, trowel, roller, etc.). Mineral finishing plaster is applied manually but nowadays increasingly by machine spraying.

The standard DIN 18550 [22] defines the technical requirements and the application of mineral base renders as well as of the finishing plaster coating systems.

6.3. Tile Adhesives

Ceramic wall cladding for building interiors and exteriors is by no mean a new invention. The first ceramic wall cladding materials in form of fresco and mosaic tiles were produced ca. 3500 years ago in Egypt, Persia, and China. Tiles provide an esthetically attractive decorative surface in combination with important functional benefits, being water resistant, tough, long-lasting, hygienic, and easy to clean. For these reasons tiles are important floor and wall covering materials in the construction industry. In 1999 ca. 4.5×10^9 m^2 were produced and laid worldwide. The most important market was Asia (1.9×10^9 m^2) followed by Europe (10^9 m^2) and America (0.9×10^9 m^2).

Mainly earthenware tiles for indoor applications (non-frost-resistant porous tiles with a water absorption of ca. 25 % according to the EN 87 [23] and frost-resistant stoneware tiles (non-porous tiles with a water absorption of ca. 1 %) for indoor and outdoor applications are used. Different types of natural stones are installed for indoor and outdoor applications. Nowadays,

the hard-pressed fully vitrified tiles (porcelain tiles) with an extremely low water absorption (< 0.1 %) and an excellent scratch, wear, and weather resistance, as well as glass tiles, are being increasingly used, mainly for outdoor applications and for floors. In addition there is a strong trend to use tiles in larger sizes (large-formatted tile, up to 40×40 cm).

Ceramic tiles and natural stones previously were exclusively laid with the thick-bed mortar technique based on job-site-mixed mortars. In this method, sand and cement are mixed together on the job site to produce a simple cement mortar with a cement/sand ratio of ca. 1/4 to 1/5. After applying (buttering) this mortar on the reverse side of the water-(pre)soaked or prewetted tile in a thickness of 15 – 30 mm, the tile buttered with the mortar is pressed to the prewetted surface to be tiled. The tiles are tapped to ensure uniform flatness of the tile surface, and thus a final mortar bed of 10 – 25 mm is obtained. This procedure not only causes a compaction of the mortar, but leads in addition to the migration of the fine cement particles into the porous reverse side of the tiles and into the porous substrate. In this way a mechanical fixation or anchoring of the tile in the mortar bed is assured, as well as anchoring of the mortar on the substrate after curing of the cement. Because this simple type of mortar has no slip resistance, tiling must be started at the bottom, and spacers must be used to obtain regular joints between the tiles.

However this method is a very time-, cost- and, material-consuming process which requires experienced craftsmen. They have to decide whether the substrate and the tiles are suitable for using this method, a certain soaking time of the tiles is required depending on their porosity, the mortar must be mixed in the correct ratio and consistency, and the right amount of mortar has to be applied on the reverse side of the tile before it is laid. More significantly, there are a lot of technical restrictions in using this technique in the modern building industry. For example, only porous and relatively small format tiles can be laid on porous, solid, and strong mineral surfaces (backgrounds) with this method due to the need for mechanical anchoring of the mortar.

Therefore, the thin-bed mortar technique today has replaced the thick-bed mortar method in most industrialized countries. After the polymer-modified prepacked dry-mix mortar has been gauged with water, it can be applied to a large area of the surface to be tiled with a notched trowel (floating technique) to give a ribbed mortar bed of uniform thickness. Due to the good water retention capacity of the thin-bed mortar (effect of cellulose ether), neither the tiles nor the substrate (background) have to be presoaked or prewetted. The tiles are then pressed into the mortar bed with a slightly twisting action. If the adhesive mortar is formulated in the appropriate way by using adequate additives, tiles that have just been laid in the fresh mortar bed will not slip. Thus, the insertion of spacers between the tiles is not necessary and tiling can be carried out from the top to the bottom. This technique creates an adhesive mortar bed of ca. 2 – 4 mm thickness, depending on the dimensions of the trowel notches used (usually $6 \times 6 \times 6$ mm, depending on the size of the tiles and the flatness of the substrate). The thin-bed mortar technique is thus more cost-effective than its thick-bed counterpart. It also uses less material, can be applied more universally, and its execution is simpler, faster, and safer. This is even true in cases where the background is uneven and has to be coated or levelled with an equalization mortar first.

With this thin-bed technique (Fig. 8) using specially designed prepacked dry-mix adhesive mortars, all technical demands of modern building industry using different types of backgrounds and covering materials under different and extreme climatic conditions can be satisfied. Today there is wide range of ceramic-tile adhesives available, depending on the substrate to be tiled and the tiles being used: standard and flexible, normal- and fast-setting, as well as special adhesives such as white mortars for fixing natural stones, waterproofing adhesives, flow-bed mortars for floor tiling, gypsum-based adhesives, and high-flexibility mortars for fresh screeds.

Figure 8. Application of a thin-bed ceramic tile adhesive (spreading the adhesive mortar with a notched trowel on a wall to be covered with ceramic tiles); picture: Wacker Polymer Systems

Dry-mix mortars for thin-bed tiling must fulfill technical requirements such as good workability characteristics, good water-retention capability, long open time and adjustability time even at high temperatures, and good non-sag properties. After curing, the cement-based adhesive mortar must provide a good adhesive and cohesive bond strength between all types of covering materials (e.g., natural stones and all kind of ceramic tiles) and various backgrounds (e.g., concrete surfaces, brickwork, lime – cement renders and base coats, gypsum, wood, old tile surfaces, gypsum wallboards, aerated lightweight concrete, particle boards, etc.). This must be guaranteed even after exposure to frost, dampness, and even permanent immersion in water. In addition to good adhesion, the thin-bed adhesive mortar must have sufficient flexibility to absorb and reduce possible tensions between the background and the tiles caused by different thermal expansion coefficients of the covering materials and the substrates as well as possible movements of the background.

These overall characteristics of a thin-bed adhesive mortar can only be achieved by prepacked polymer-modified cementitious dry-mix mortars containing cellulose ethers as additives and redispersible powders as a polymer binding agent. Typical basic formulations for a standard and a high quality flexible ceramic tile adhesive are given in Table 5.

Table 5. Typical formulations for ceramic-tile adhesives

Adhesive type∗	A	B
Portland cement (OPC)	45	35
Silica sand (0.05 – 0.5 mm)	53.1 – 51.6	59.6 – 57.6
Cellulose ether (viscosity ca 40 000 mPa s)	0.4	0.3
Redispersible powder	0 – 4	5 – 10
Additives (if required for special performance)	(0 – 5)	(0 – 5)

∗ Type A = standard polymer-modified ceramic-tile adhesive, Type B = flexible, high-quality, polymer-modified ceramic-tile adhesive.

The most important technical requirements in Europe for a ceramic tile adhesive (besides workability) and the test methods are summarized in Table 6.

6.4. Tile Grouts

Tile grouts are used to fill the joints between tiles or natural stones laid on walls or floors. Cement-based tile grouts with appropriate formulations are suitable for interior and for exterior application. In combination with the tiles they must provide an optically attractive suface and must perform physical functions. The tile grout must be capable of reducing stresses within the whole wall or floor covering material, it must protect the materials and layers under the tiled surface against mechanical damage and the negative influences of water penetrating into the whole construction. Thus a cementitious grout must have good adhesion to the edges of the tiles, low shrinkage, sufficient deformability or flexibility, high abrasion resistance, good toughness and cohesion, low water absorption, and an excellent workability (low stickiness of the wet mortar). According to their application, two main types of tile grouts can be classified (Table 7).

For white and colored tile grouts, white cement is used as a mineral binder. Alkali-resistant pigments such as iron oxides should be used for colored grouts. Appropriate carbonate fillers can be used additionally or even exclusively instead of silica sand as a filler. To reduce the risk of efflorescence, the use of hydrophobing agents is very helpful, and microsilica or trass can additionally be added. The main technical requirements for tile grouts are summarized in Table 8.

Table 6. Summary of European standards for ceramic-tile adhesives

6.5. Exterior Thermal Insulation Composite Systems

External thermal insulation composite systems (ETICS) or external insulation and finishing systems (EIFS) were developed in Europe in the early 1970s. The first oil crisis in Germany in 1973, together with financial support from the government for homeowners, helped tremendously to promote the system. From 1973 to 1993 ca. 300×10^6 m^2 of facades in the Federal Republic of Germany were equipped with ETICS [24], and more than 18×10^9 L of heating oil was thus saved. Apart from saving energy, emissions of pollutants and CO_2 are reduced.

ETICS also significantly increases the comfort while living in a building due to a more constant temperature and humidity over the seasons. It reduces significantly building damages by decreasing the temperature variations in the external wall construction and combined with less condensation of dampness allows to reduce the overall building costs. Therefore, thermal insulation is not only a sensible investment in new buildings, but also a good renovation measure, especially if the facade has to be renovated anyway.

The first ETICS, introduced in the 1970s, consisted of a dispersion-bound paste adhesive to which cement was added at the construction site. This compound was used to fix expanded polystyrene panels to the walls to be insulated. The same product and procedure was used to embed the fiber-glass mesh that serves as a reinforcement in the reinforcement layer or base coat on top of the fixed thermal insulation panel. In earlier years mainly dispersion-bound synthetic resin plasters were applied as a finishing coat after the base coat had been primed.

However, in practice many mistakes occurred when using this system, in particular during the mixing of the dispersion-bound paste adhesive with cement at the construction site. With this system it is not possible to always produce a homogeneous mixture with a constant polymer to cement ratio, and adhesives and base coats with different compositions are thus obtained. This results in inadequate product characteristics and possible damage to the facades due to insufficient adhesive bond strength or flexibility. This argument also apply to the two-component systems, in which a water-based dispersion is added to dry-mix mortars at the construction site. For

Table 8. Important requirements, test methods, and standards for cement based tile grout mortars

	Standard	Requirements
Grouts for tiles – definitions and specifications	prEN 13888	
Determination of water absorption	prEN 12808-5	water absorption (WA) determined with $16 \times 4 \times 4$ cm prisms; requirements: fundamental characteristic: WA after 30 min < 5 g; WA after 240 min < 10 g additional characteristic: WA after 30 min < 2 g; WA after 240 min < 5 g
Determination of resistance to abrasion	prEN 12808-2	abrasion tester according to EN102; requirements: fundamental characteristic: volume removed during test $< 2000\,mm^3$ additional characteristic: volume removed during test $< 1000\,mm^3$
Determination of shrinkage	prEN 12808-4	shrinkage determined with $16 \times 4 \times 4$ cm prisms after 28 d sc; requirement: < 2 mm/m
Determination of flexural and compressive strength	prEN 12808-3	flexural (FS) and compressive strength (CS) determined with $16 \times 4 \times 4$ cm prisms after 28 d sc and freeze – thaw cycles; requirements: FS $> 3.5\,N/mm^2$; CS $> 15\,N/mm^2$

these reasons, togther with the above-mentioned principle disadvantages of two-pack systems, today the polymer-modified cement based dry-mix mortars have almost completely substituted all other systems for ETICS.

Classic ETICS consist of the following components:

- Adhesive for fixing the thermal insulation panels, mainly expanded polystyrene, on the wall (depending on instructions and technical guidelines, additional mechanical fixing with special dowels may be necessary).
- Base-coat for embedding the reinforcement mesh on top of the thermal insulation panels (mechanical protection of the thermal insulation panels).
- Mineral finishing coating (mainly cementitious plasters or stucco with different structures).

A typical formulation (in wt %) for the adhesive and base-coat mortar is given in the following:

Portland cement	20 – 30
Filler (silica sand and/or carbonate filler, 0.05 – 0.5 mm)	64.7 – 75.9
Cellulose ether	0.1 – 0.3
Redispersible powder	4 – 5
Additives	0 – 3

The combination of individual components of an ETICS must always be seen as a whole. Thus the adhesive, thermal insulation panels, embedding mortar, fiber mesh, primer (or keycoat if necessary), dowels (if an additional mechanical fixing is required), and the finishing coat must be carefully adjusted to each other and must be tested and approved together as a system. Therefore, it is not permitted to combine individual components from different sources to create an ETICS which has not been tested and approved as a whole system.

Figure 9 shows a typical composition of a ETICS.

Figure 9. Typical components of a ETICS (Wacker Polymer Systems)

To meet the technical requirements, ca. 4 – 5 % of organic binder in form of a redis-

persible powder is used for the adhesive mortar and the base coat. This means that apart from the required good adhesion of the cementitious mortar on the substrate and on the insulating polystyrene panels, a sufficient deformability (flexibility) and a high degree of impact resistance of the mortars are achieved as well.

A large choice of different materials and systems are available nowadays as finishing coats for the ETICS. Apart from the classic dispersion-bound plasters, available in many structural variations and colors, mainly mineral cement – lime plasters or stuccoes, silicate plasters, and to a certain extent silicone resin plasters are used.

Various countries have differing regulations and specifications for ETICS. At present a European standard is being prepared for external thermal insulation composite systems [draft from European Organisation for Technical Approvals (EOTA)]. It will describe all specifications for the individual components of the system and the overall composite system itself (e.g., physical and construction specifications as well as techical requirements like water absorption, behavior under hydrothermal stress, inflammability, water-vapor permeability, adhesive strength, impact resistance, etc.).

Worldwide, new thermal insulation regulations (e.g., WschVO in Germany [25]) furthermore establish minimum requirements for the K-value (thermal insulation value) of the external walls of new buildings. For concrete and bricks walls these binding minimum requirements can often only be met by the additional application of an ETICS, and this will lead to a further growth in thermal insultation systems. Even in countries with an high average temperature, thermal insulation composite systems are becoming popular for saving energy for air-conditioning.

6.6. Powder Paints

The use of liquid dispersion paints is well known and has proven itself in practice since their invention in the 1950s, and today this is the leading technology for interior and exterior paint application. As a sole binding agent for his type of products aqueous dispersions based on styrene – acrylate, vinyl acetate ethylene, or other copolymers are used.

In DIN 55945 surface coating materials such as laquers and paints are defined, classified, and characterized. Paints according to this standard are compounds in liquid and pasty form, based on solvents, binding agents, pigments, fillers, and additives, but including powder-form coating materials as well. Paints can be classified as:

- Solvent-based coating materials
- Water-based coating materials (laquers, paints)
- Spray-applied powder coatings
- Paints and coating materials in powder form (powder paints) to be mixed with water before application

Powder paints were known for many decades before the invention of the liquid dispersion paints. In the early days of the powder paints the binder was either of organic origin (e.g., distemper paint based on glue) or of inorganic origin (e.g., mineral paints based on the mineral binders hydrated lime and/or cement). For a long time the mineral binder was modified with organic binding agents (casein, cellulose ether, starch ether) to improve the technical characteristics of the mineral coating material.

Natural organic binders have since been replaced with much more efficient synthetic polymer binders in the form of redispersible powders, and this has again led to an increasing importance of powder paints. Redispersible powder as organic binder is used as the sole binder in powder dispersion paints and for the modification of mineral powder paints based on cement, hydrated lime, or water glass (silicate powder paints) to improve their technical performance and durability.

Powder dispersion paints were first used on building facades in Austria in the 1960s and later in Germany. They provide almost the same characteristics as liquid dispersion paints, but offer all the advantages of a powder system. Powder dispersion paints are used for interior and exterior applications. The most important difference in formulation is the content of polymer binder. The higher the polymer content, the better the adhesion and the higher the wet-scrub resistance of the paint.

Like typical dry-mix mortars, powder paints are supplied in paper bags or in silos to the job site and are gauged with water befor use and are applied by brush, roller or spraying.

Table 9. Important test methods and standards for (powder) paints

	Standard	Comments
Definitions	DIN 55945	definitions, composition, types of painting materials,
General requirements	DIN 53778	general requirements concerning workability, capability of dilution, tinting, compatibility with pigments, minimum temperature of application, recoatability, gloss, hiding power
Water absorption	EN ISO 15148	coefficient of water absorption $W < 0.5\,\mathrm{kg\,m^2\,h^{0.5}}$ and $W \cdot S_\mathrm{d} < 0.2$ $\mathrm{kg\,m\,h^{0.5}}$ for exterior application (EN ISO 15148 substitutes DIN 52617)
Water-vapor permeability	EN ISO 12572	diffusion-equivalent air-layer thickness $S_\mathrm{d} < 2\,\mathrm{m}$ (EN ISO 12572 substitutes DIN 52615)
Wet-scrub resistance	DIN 53778	$>$ 1500 cycles for indoor application, $>$ 5000 cycles for outdoor application and for scrub-resistant paints

Table 9 summarizes the most important standards and technical requirements for powder paints.

6.7. Cementitious Waterproofing Sealing Slurries

Water in liquid or in vapor form is the most destructive weathering element for building materials such as concrete, masonry, and natural stones.

Traditional sealing and waterproofing systems (e.g., according to DIN 18195) include bituminous materials, plastic waterproofing foils, and metal tapes for interior and exterior applications. Different types of materials can be used to seal and protect the surface of buildings or their structural components against the intrusion of dampness and water. Nowadays products for this purpose are based on reactive resins like epoxy and/or polyurethane, dispersions (paintable waterproofing membranes), and mineral binders like cement, which are known as waterproofing membranes or sealing slurries.

Cementitious waterproofing membranes have been successfully used for more than 40 years in Europe. The structures to be protected were either exposed to periodic or long-term wetting (surface water, seepage water), low hydrostatic pressure (soil dampness), or in combination with appropriate engineering even high hydrostatic pressure. Cementitious membranes (slurries) are used to waterproof wet rooms and water tanks, and due to their excellent weathering resistance also for exterior surface protection. Further typical applications are the sealing and waterproofing of basement walls, of swimming pools, as well as walls and floors in bathrooms, and on balconies and terraces as a waterproofing layer to be tiled over. Some of the main advantages of cement-based waterproofing membranes are their excellent resistance to water (even if exposed permanently), excellent long-term weathering resistance, good scratch resistance, good load-carrying capacity and much higher water-vapor permeability than most of the other systems.

Figure 10 shows a typical application of a cementitious waterproofing sealing slurry by brush.

Figure 10. Typical application of a cementitious waterproofing sealing slurry by brush (Wacker Polymer Systems)

Cement-based waterproofing slurries are easy to use, nontoxic, provide a fully bound and monolithic surface without joints, and can be

easily applied on substrates with complex surface shapes. In contrast to other systems, cementitious waterproofing slurries can even be used on damp and wet mineral surfaces. Their physical properties are also less temperature-dependent compared to bitumen-based materials. So far there are no standards available for these alternative sealing products, but national guidelines of mortar associations are well accepted in the building industry [26].

Simple, non-polymer-modified cement-based slurries are still used for protection against surface water, but they are not suitable for sealing against water under hydrostatic pressure. To improve the poor adhesion, the poor water tightness, and the extremely low deformability and flexibility of these unmodified systems, polymers are added in form of liquid dispersions on the job site or as a redispersible powder already mixed with the dry-mix mortar. Special additives in these dry mix mortars include water-retention agents, thickening agents, and rheological additives.

Today standard or rigid mineral waterproofing slurries are polymer-modified, prepacked dry-mix mortars with a high cement and relatively low polymer (redispersible powder) content. They are used for mineral substrates which are dimensionally stable, sound, and solid without risk of crack formation, movement, or dimensional changes such as shrinkage. Developments in the late 1970s led in Europe to flexible waterproofing slurries, which to a certain extent are capable of bridging small cracks (up to ca. 1 mm) in the substrate. The flexibility of such products strongly depends on the polymer to cement ratio and on the flexibility of the polymer itself. Flexible and highly flexible waterproofing cementitious slurries are used on substrates that are still subject to shrinkage, vibration, movement, stress, and crack formation, and on substrates that are difficult to coat, such as wood, steel, aerated lightweight blocks, and gypsum. Due to their high polymer content (up to 40 wt % of the total formulation), they have a high diffusion resistance and are chemically resistant to chloride, sulfate ions, carbon dioxide, or other aggressive substances. In central Europe flexible cementitious waterproofing sealing slurries represent the last domain for two-component (two-pack) systems, which are based on prepacked dry-mix mortar and liquid admixes. However, even in these high-polymer products, there is a strong trend towards one-pack systems in form of polymer-modified dry-mix mortars.

6.8. Self-Leveling Underlayments and Screeds

Self-leveling underlayments (SLUs) are from a technical perspective probably the most complex field for dry-mix mortars. On a given uneven substrate (i.e., screed or surface to be refurbished), self-leveling mortars have to provide a suitable, smooth and solid substrate for applying all kinds of flooring materials like carpets, wooden parquet, PVC, tiles, etc. Self-leveling underlayments should be applicable in an easy and efficient manner, even for large areas. Therefore, the SLU material has to have very good flow characteristics, and self-leveling and self-smoothing properties. In addition, it should set and dry quickly so that the flooring material can be applied on top of the hardened mortar after only a few hours. The SLU mortar should adhere to all kinds of substrates and exhibit low shrinkage, high compressive strength, and good abrasion resistance.

The technical requirements for SLUs range from very simple to highly sophisticated products. They vary in thickness from a very thin layer of 1 – 10 mm (feather finish, self-leveling/troweling mortars and underlays), up to 60 mm for self-leveling screeds, which are always applied by machines (mixing and pumping in one set up).

The screeds are used as a load wearing base in a thickness from 30 to 80 mm, and are thus high-volume-application mortars. These mortars can be based on cement or gypsum (anhydrite) as mineral binder, the latter providing underlayments with a high dimensional stability (low or even no shrinkage). The set time ("walk-over time") of these materials varies from normal/regular setting to fast-setting products. Normally this depends on the requirements of a specific job, that is, the flooring material can be laid on the SLU in a certain time frame. The shorter the setting and drying time, and the thicker the mortar is applied, the more complicated and expensive the formulation becomes. Self-leveling compounds for underlayments and screeds are based on special hydraulic binders like Portland

cement (OPC), high-alumina cement (HAC), and gypsum (anhydrite), to achieve fast curing and drying by avoiding excessive shrinkage or expansion.

So far there are no standards on self-leveling underlayments (SLU) in Europe. However, the technique and its application have been well known for many years, and exclusively polymer-modified prepacked dry-mix mortars are used for this application.

6.9. Patching and Repair Mortars

Concrete is a very versatile, long-lasting, and durable building and construction material if it is applied according to the state of the art. In the past, and even today, unfortunately, repeated disregard of the fundamental principles of concrete and structural concrete application still leads to severe and serious damage in the building industry. The cost of the repair of concrete structures has dramatically increased over the last 30 years in all industrial countries. In Germany approximately 20 % of the cost of the volume of structural concrete work is attributed to the repair and maintenance of existing buildings and structures. The degradation of structural concrete is caused by corrosion of the steel reinforcement due to carbonation of concrete caused by atmospheric carbon dioxide and other aggressive media (e.g., SO_2, acid rain). The corroded steel reinforcement increases in volume and splits off the overlying concrete, thus destroying the structure.

In the construction industry concrete repair work can be classified into two types:

1) Repair of concrete which does not contain steel reinforcement and which does not have load-bearing functions. It is normally carried out for aesthetic reasons (cosmetic repair work) only, with patching mortars or patching compounds.
2) Repair and reconstruction of damaged reinforced and load-bearing concrete structures to maintain and reconstitute their structural stability and function. This is carried out in stages with different kind of mortars, which are part of a "concrete rehabilitation system" (typical applications: repair work and rehabilitation of bridges, parking decks, tunnels, etc).

Patching mortars for reprofiling and cosmetic repair are based on dry-mix mortars. Usually cement-based mortars are used for indoor and outdoor applications, whereas gypsum-based products are only used for some specific indoor applications (cosmetic repair), i.e., for filling small holes, voids, cracks and cavities to restore the original dimensions.

To guarantee the durable and reliable repair of structural concrete, concrete rehabilitation systems must restore the corrosion protection of the steel reinforcement (alkaline environment), reprofile the concrete structure, restore its load-bearing functions, and finally restore the protection and thus durability of the whole construction (protection against weathering and environmental damage caused by CO_2, SO_2, Cl_2, deicing salts, etc).

For the rehabilitation of structural concrete three types of mortars are used today: cement-based concrete mortars (CC; mostly applied as a shotcrete mortar), polymer (modified) cement concrete (PCC) as prepacked dry-mix mortars, and epoxy cement concrete (ECC).

Today mainly PCC mortars are used for the rehabilitation of concrete structures. These mortars can be applied by hand as well as by machine, in a wet or even a dry spraying shotcrete process. Different kind of mortars delivered as dry-mix mortars with different characteristics and functions are used as the components for concrete rehabilitation systems:

- Primer and adhesion promoter for the reinforced steel (polymer-modified cementitious slurry or epoxy-based coating materials)
- Adhesion-promoter slurry (primer or key-coat) for the concrete to be repaired (polymer-modified cement based slurry)
- Restoration and reprofiling mortar (polymer-modified cement-based mortar)
- Fine stopper or smoothing mortar (polymer-modified cement-based mortar containing fine aggregates)
- Protective and finishing coat (dispersion paints, crack overbridging paints, cementitious waterproofing sealing slurries, etc.).

So far mainly national guidelines implemented by various organizations and regulations are relevant to the requirements for concrete-repair systems [27]. Concrete rehabilitation sys-

tems are subjected to an official approval according to relevant laws and regular quality supervision from independent test institutes.

7. Market Aspects

Precise data on worldwide production and consumption of dry mortars are not available, although for Germany, France, and Italy calculations of the production are known. According to ref. [28] the production of dry mortars in 2001 was 10×10^6 in Germany, 3×10^6 in Italy, and 2.7×10^6 in France, and total consumption in

Western Europe was 30×10^6 [28] or $35-40 \times 10^6$ according to other estimates. Worldwide consumption lies in the range of $50-60 \times 10^6$ [28], or $(60-70) \times 10^6$ according to other estimates.

With increasing local working costs the ratio between dry mortars and mortars mixed on site is increasing, as the application of dry mortars requires less time for the same work. Worldwide dry mortar consumption is increasing. While growth was strong in central Europe from the 1960s to the 1980s, nowadays growth is mainly in Eastern and Southern Europe, as well as in parts of the Asian and Latin American market.

Pigs are devices which are inserted into and travel through a pipeline, driven by a liquid or gaseous propellant. Installation and operation of pipelines would not be possible without pigging technology. Applications of pigging include sweeping liquids from pipelines, removing condensate, separation of products, inspection, cleaning, and repair. The action of products and/or propellants on pig materials can lead to physical and chemical reactions.Depending upon function, different designs of mechanical and intelligent pipeline pigs are used. Smart pigs are used above all for in-line nondestructive testing of pipelines. Some basic risks must be taken into account when a pigging system is planned.Examples for industrial pigging units are found in food and beverage industry, cosmetics, pharmaceuticals, and in the chemical industry.

1. Introduction

In *pigging*, the contents of a pipeline are pushed by a snug-fitting plug (*pig*) with the goal of removing the product almost completely from the pipeline. The pig is propelled through the pipe by a gas or a liquid (propellant). Apart from the cleaning, pigs can be used to separate different products that are transported in the same pipeline.

Pigging technology was originally developed for the oil industry and has been employed for cleaning pipelines for more than 100 years. Since then, pigging technology has found increasing application in the chemical and other industries.

A *pigging unit* usually consists of the following components:

- The pig
- Piggable pipes with piggable valves
- Pig loading and unloading station
- Propellant supply
- Control system

In the simplest case the pigging unit (Fig. 1) consists of a single pipeline that is traveled by a pig. All components of a pigging unit must be piggable.

Pigs are available in numerous designs, sizes, and materials: From simple spherical pigs, mandrel pigs, and separating pigs to in-line testing and inspection pigs; and from fluid-driven pigs to self-driven camera vehicles. The range of applications of pigs is thus very large.

The most important applications of pigging are:

- Sweeping liquids from pipelines.
- Removing incrustations and deposits.
- Removing condensate (gas pipelines).
- Filling/emptying of a pipeline with plug flow.
- Separation of products, pumped one after the other in the same pipeline (e.g., product A – pig 1 – product B – pig 2 – propellant). This process is called batch pigging.
- Inspection, detection, and observation.
- Cleaning.

Figure 1. Schematic of a pigging unit

– Measurement and control.
– Repair.

The applications of industrial pigging units encompass four major tasks:

– Several products are pumped through a single pipe
– Product is removed from a pipe
– Rinsing the section of a pipeline between two pigs with a detergent and/or a solvent (tandem pigging)
– Prevention or reduction of foaming

2. Definitions

A *pigging unit* is the total mechanical, and electrical equipment and instrumentation, which is needed for the execution of pig travel. It is a part of an entire plant that cleans, separates, and/or removes liquid substance from at least one pipe. It consists of one or more piggable pipelines including piggable valves, the receiving and launching stations, the control system, and the pig.

Piggable lines can be simple (one piggable line without any branching), branched (consisting several T-piece valves for product inlet and outlet), or with switches (valves with junctions for both pig and product flow).

The *propellant* is the medium which propels the pig. Propellants can be gaseous (compressed air, nitrogen) or liquids such as water (also with additives, inhibitors, or fully demineralized), product, cleaning agents, or solvents.

Pigs, driven by a gas, behave differently to liquid-propelled pigs. Due to their compressibility gaseous driving media lead to uneven pig movement. With liquids as driving medium, ideal plug flow develops behind the pig, and this leads to homogeneous pig movement.

The term *pigging system* refers to the different pigging procedures that are possible in a pigging unit, i.e., the temporal sequence of individual operating steps. A distribution is made between open and closed pigging systems, and between one- and two-pig systems.

In an open pigging system (removable pig) the pig can travel through the pipe only in one direction (Fig. 2). At the receiving station the pig is removed and returned externally to its starting station.

In open pigging systems, pigs with conical, cup-shaped seals are generally used which can be driven only in one direction. Often several pigs are present at the launching station, which are collected at the receiving station for return. The cleaning of the pigs is carried out manually outside of the pigging unit. Open systems are

Figure 2. Open pigging system (schematic)

particularly suitable for long lines (> 1 km) in the chemical industry, e.g., from a tank farm to a ship at a loading jetty or long-distance pipelines.

In a closed pigging system the pig remains during its total service life in the line. Only pigs whose form enables movement in both directions are suitable. The closed pigging system is versatile, e.g., piggable diverter valves can be used to construct a branched pigging unit.

One-pig systems (OPS, Fig. 3 A) can be open or closed. In two-pig systems (TPS, Fig. 3 B) the two pigs can be driven in the same direction with or without interpig spacing or in opposite directions through the line.

3. Pigs

Pigs are devices which are inserted into and travel through a pipeline, driven by a liquid or gaseous propellant. The pigs slide on a thin liquid film (micrometer range) and clean the pipe with two or more narrow lips. The pigs are thicker than the internal diameter of the pipe and are pressed into the piping. The resulting strain which depends on the diameter and type of pig and amounts to ca. 3 % prevents aquaplaning. Thus a high degree of cleaning is ensured.

The chemical and physical characteristics of the products to be pigged influence the selection of the *pig materials*. Depending on the application different pig materials are used. The most frequently employed materials for pigs are elastomeric polymers.

Pig designs can be classified as one-piece and multicomponent. In one-piece pigs, body and cleaning lips from a unit, while multicomponent pigs consist of a central body that can be equipped with different cleaning elements.

Spherical pigs, solid cast pigs, lipped pigs, cylindrical pigs, pigs with exchangeable lips, conical seal pigs, and various specialty pigs are available. Depending on the required degree of cleaning the size of the pipe, and the system pressure, a suitable pig is selected.

The *solid cast pig*, the main features of which are described in Figure 4, is among the most frequently used one-piece pigs. It is adequate for most pigging processes. Solid cast pigs are very durable and are equipped with two inflexible lips that clean of the pipe. Solid cast pigs are pressed into the pipe with a prestress and can be driven bidirectionally. High service lifetimes can be achieved. Polyurethane has the best mechanical properties for these pigs.

Exchangeable-lip pigs (Fig. 5) are the simplest examples of multicomponent pigs. They have a solid body, made of plastic or metal, with two or more removable flexible lips. Af-

Figure 3. A) Closed pigging system (OPS); B) Closed pigging system (TPS)

ter changing the worn lips, the solid body can be used again.

Special pigs are used in the oil industry, in sterile areas, in the foodstuffs industry, and with bulk materials for cleaning purposes and for blockage-free transport.

The different chemical and physical characteristics of piggable products crucially affect the selection of materials for pigs.

The action of products and/or propellants on pig materials can lead to physical and chemical reactions. The results of physical processes are revealed by changes in weight, volume, and dimensions, and the influence of chemical reactions by changes in hardness, ultimate tensile strength, and fracture strain. If no suitable pig material is found, then an industrial pigging unit must be dispensed with.

4. Valves

In a piggable piping system the selection of the piggable valves is particularly important. They must be optimally adapted to the application. Apart from the general requirements for valves, such as tightness, low leakage, smoothness of operation, and precision the piggability of the valves must be ensured, e.g., by having:

- The same internal diameter as the pipeline
- A centerable flange
- Accurate adjustability of plugs in stopcocks and switches
- Guiding rods at valve outlets

The piggable valves are classified as standard and special valves:

Figure 6. Loading and unloading station (company Pfeiffer)

Standard valve	Special valves
– Stations	– Crossing of two piggable pipes
– Branches	– Pig receiving station for loading arms
– Pig traps	– Pig receiving station for filling valves
– Switches	– Manifold
	– Valves for the sterile areas

The *pig loading and unloading station* (Fig. 6) can be at any end of the pigging system. At the loading and unloading station the pig is introduced into or removed from the pigging system, and can also be driven through the pigging system by a propellant.

Before the pig is changed, the valve or the pipe must be completely depressurized or separated from the piping system by a safety valve. Insertion and removal of pigs must be easy, fast, and safe. Fittings for cleaning agents, as well as pig sensors or mechanical pig tracers for detecting the pig, must be incorporated in the valve.

The station simplifies the pig loading and unloading substantially by means of the integrated shut-off ball valve. The ball has a blind hole and can be rotated by 180 ° for removing and inserting the pig. The diameter of the blind hole is larger than the outer diameter of the pig and the

internal diameter of the piggable pipe so that the pig can be inserted easily. The transition between valve and pipe is conical, so that the pressure of the propellant pushes the pig into the piggable pipe.

If product is to be removed from or introduced into a piggable pipe, then a *branch* is required. Usually the branch is arranged vertically with respect to the pipe axis. Examples of branches are the T-ring valve and the throughput piston valve.

The *T-ring valve* (Fig. 7) is a dead-space-free special valve that functions as a check valve, piggable T-piece, and pig trap. The straight-through passage can be pigged without a dead space, whereby the valve is closed. The T-branch can be shut off by the sliding ring, which also stops the pig. A further check valve at the T-piece is not required.

Figure 7. T-ring valve (company I.S.T.)

The *throughput piston valve* (Fig. 8) combines the functions of a piston valve and a pig retainer or pig stopper in one valve. In the closed state the piggable pipe runs smoothly without dead space through the piston valve. In the open state the product can be withdrawn downwards and the pig thereby is held on the piston of the valve.

Figure 8. Throughput piston valve (company Kiesel)

In contrast to product branches, *switches* divert both product and pig. An example is the three-way switch (Fig. 9).

Figure 9. Three-way switch (company Pfeiffer)

Manifolds allow piggable pipes to be connected with nonpiggable pipes. Manifolds are required in multiproduct units for mixing, filling, and shipping procedures.

The full-system manifold (Fig. 10) is closed and piggable on one side. The full-system section consists of nonpiggable rectangular ducts for product feeding. At right angles to these ducts are the piggable pipes, which are connected at the intersection by means of ring valve. This ring valve opens the connection from the product feed duct to the piggable part of the manifold and simultaneously acts as a pig receiving station. Manifolds make it possible to connect and distribute up to 50 feed pipes to as many as 20 piggable pipes in a single module.

Figure 10. Full-system manifold (company I.S.T.)

5. Piping

In a pigging system the piggable pipes, pipe bends, and joints are of major importance. The quality of the overall system determines the cleanness of the piping after a pig travel.

Therefore, all important boundary conditions are specified in standard DIN 2430 (available in English): Piping for Pigging Systems: Part 1: Pipes and Tube Bends, Part 2: Fittings, Part 3: Testing Prior to Commissioning.

The preferred materials (DIN 2430) are the stainless steels 1.4307, 1.4404, as well as AISI 304L, and AISI 316L.

The characteristics specified by the manufacturer are checked in the important test pigging.

In the test pigging, propellant pressure and time are measured, and thus pressure peaks, caused, e.g., by flange misalignment, welding seam dips, pipe bends, valves, dents, etc., can be detected and located. The ratio of back pressure to peak pressure is a measure for the quality of manufacturing and erection of the piggable pipe.

Test pigging is a component of the function guarantee and is required by all companies which design, supply, and erect industrial pigging units.

6. Control System

Planning the control system for a pigging unit requires knowledge of this special technique. Control of a pigging unit should preferentially be automatic by means of a distributed control system (DCS) or, for smaller systems, a programmable logic controller (PLC). A field bus system connects the field devices (actuators and sensors) directly to the control system. Monitoring and operating components are necessary to supervise the locations and motions of the pigs and to check the valve settings, pump running information, and tank level indicators.

Figure 11. Principle of a magnetic pig indicator

One of the most important sensors of a pigging system is the pig detector (Fig. 11). For this purpose a permanent magnet is installed inside

the pig. Outside the line magnetic-inductive indicators are mounted at suitable locations (e.g., pig stations, junctions). To avoid faulty measurements, the material for lines and valves must not be magnetizable (paramagnetic).

All the other sensors (pressure, level, temperature) found in a pigging system are regular commercial instruments. Recent developments in the instrument technique of the Coriolis mass flow meters permits this technology to be used directly in piggable lines. Ultrasonic flow measurements, which are applied outside from the pipe, can also be used.

7. Decision Criteria for Pigging

Apart from technical necessity, the economy of a pigging system is the focus of attention. It is above all crucial, that the new technology brings an advantage on a long-term basis over a competitor. Therefore, all operational criteria must be checked.

In the case of long pipes, multiproduct systems, or batch operation the economic advantages of a pigging system become particularly apparent:

- A single line is used for several products (saves on investment costs and space requirements)
- Easy emptying of the line with products which can freeze, condense, decompose, or polymerize
- Dispensing with insulation and/or tracing (line heating)
- Time savings compared to emptying the line by a manual procedure
- No rinsing procedures and/or substantially lower amounts of cleansing agents, lower costs for wastewater treatment, lower incineration costs, reduction of product losses
- No need for slopes and syphon—free installation to be able to empty the pipeline completely

8. Example of an Industrial Pigging System

A chemical production plant produces several 100 000 t/a aqueous urea – formaldehyde condensation products, mainly for the chipboard industry. The entire complex (Fig. 12) consists of:

- The production plant consisting of production intermediate vessels and a manifold station inside the building.
- Two large tank farms, connected by pipes to the process building. The pipes are up to 300 m long.
- Loading stations for tank trucks and rail cars to be filled from the tank farm.

The individual pigging lines were equipped with the two-pig systems without any detergents. In the production plant, on the pipe racks, and inside the tank farms there are ca. 2000 m of piggable lines. Within the production plant there are the following 4-inch piggable lines:

- From vessel group A to the manifold (ten three-way switches)
- From vessel group B to the manifold
- From the manifold to tank farms I and II

Between the tank farms and the loading stations there are the following 6-inch piggable lines:

- Between tank farms I and II
- From three groups of tanks to tank-truck loading
- From three groups of tanks to rail-car loading

Other conditions:

- Propellant: product or compressed air (0.4 MPa g) (g means gauge, i.e., overpressure)
- Pig-travel frequency: several times daily
- Cleaning degree: D [1]
- Solid cast pigs
- Two-pig system

The pigging systems has been in successful operation for more than 20 years, and has completely fulfilled its purpose:

- Using one pipe for several products of a product family
- Emptying and cleaning of the pipes by almost complete removal of the products
- Rapid product change and perfect separation of the products among themselves
- Avoidance of product loss by rinsing procedures
- Prevention of condensate developing and thus of blocking of pipes
- Substantial savings in wastewater costs
- Maintenance of high product quality

Figure 12. Example of a branched pigging system

9. Special Fields of Pigging Technology

Pigging in Hygienic and Sterile Applications. The term "hygienic and sterile pigging" refers to all applications in which special requirements must be fullfilled concerning cleanness and hygiene up to the extremely high requirements (e.g., GMP, FDA regulations) of sterile technology.

This particularly applies to the food and beverage, cosmetics, and pharmaceutical industries, including biochemistry and genetic engineering, as well as to special applications in chemical plants.

In fully automated processes in the food and beverage industry, the cleaning procedure is of the same importance as the production itself for hygienic reasons. Cleaning must take place regularly, often daily, to guarantee the required freedom from microorganisms. The products are predominantly of high value, so that product losses must be minimized. Cyclic cleaning procedures lead to high disposal costs.

Pipes in sterile technology must be extremely smooth inside and outside; the used fittings and valves have to be free of any dead space. Pigging, especially with closed piping systems, is especially suitable as an automable cleaning method for pipes in sterile plants.

Examples applications for industrial pigging units:

Food industry:	Yogurt, cheese, mustard, paste, jam, chocolate
Beverage industry:	Dairies, breweries, and wine cellars, syrups, fruit juices and cola concentrates
Cosmetics:	Sun screens, shampoos, lotions, creams, toothpastes
Pharmaceuticals:	Ointments, cough mixtures
Chemical industry:	Cleaning agents, detergents, vitamins, dispersions, paints and coatings

Pipeline pigging is the oldest field of pig applications.

Pipelines are used for the transport of primary energy and pumpable bulk goods. They can be used exclusively for the transport of only one product, but there are also multiproduct pipelines (e.g., different crude oils).

Pipelines (long distance lines) have other characteristics than the pipes in chemical plants. Apart from the length and the diameter these are:

– Pipelines are laid in the landscape and thus they are not free of syphons (i.e.,

not automatically emptiable). An installation without syphons is absolutely impossible, while within the chemical industry a limited syphon-free pipe installation can be achieved. The volumes of the syphons are very large (field-erected bends).
- The holdup of a pipeline is extremely large. Mass and/or flow meters are prescribed for balancing.
- Large parts of the pipeline are not accessible from the outside; this particularly applies to the offshore region.
- Industrial pipes contain substantially more fittings (bends, branches) and valves.
- Pipelines are used for few products: crude oil, refined oil, natural gas, and water, whereas the pipes in industrial plants are used for the total spectrum of chemicals.
- Pigging technology and pigging systems are substantially more complex with industrial pigging units.

A clear distinction between long-distance lines and the pipes of a chemical plant is not possible, since in practice a wide overlap exists. Also within chemical plants there can be extremely long pipelines of large nominal size, for example, naphtha lines for the cracker feed between a ship unloading facility and the process plant.

Pipelines are divided into onshore, offshore, and subsea lines, each having special requirements for strength, resistance, and installation technology. For the operation and inspection of such lines the pig must fulfill the most diverse functions.

Usually a pipeline is divided into several sections, separated by stations. In pipeline technology these stations have the ability shut the line off section by section, to create the line pressure (compressor and/or pumping stations), as well as control measurements. The station also permits pig travel. The longest distance between two pigging stations at present is approx. 800 km.

Installation and operation of pipelines would not be possible without pigging technology. Numerous tasks can only be solved economically with pigs; pipeline technology is closely connected with pigging technology, and every pipeline is equipped with pig stations. Therefore, the first applications of pigs coincided with the building of the first pipelines. Around 1870 in the USA the first long-distance pipelines for crude oil were laid, and the term pipeline pig was used for the first time.

Pigs are used in the erection phase and later when operating, inspecting, maintaining, and repairing the pipeline:

- During fabrication: Removal of coarse dirt, removal of liquids, drying, final inspection
- During start up: Complete flooding for pressure testing, calibration of volumetric flow meters
- During operation: Cleaning (removal of deposits), condensate removal, separating different products
- During inspection: Checking geometry; detection of corrosion, erosion, and cracks; leakage detection
- During repair: In situ in-line coating, corrosion inhibition, plugging of pipeline sections, shutting off lines

Depending upon function, different designs of mechanical and intelligent *pipeline pigs* are used. Separation pigs and cleaning pigs belong to the group of mechanical pigs, whereas detection pigs and inspection pigs are classified as intelligent pigs.

Different methods are available for pig detection in pipelines: mechanical, ultrasonic, and radioactive detection, and transmitter/receiver systems. Since pipelines mainly consist of ferritic steel, pig detection by means of built-in permanent magnets, as in industrial pigging units, is not possible.

Solid cast pigs for use in pipelines are mostly made of open-cellul polyurethane, rather than the solid plastics of the industrial pigs. Polyurethane foam pigs are available in different densities and with various configurations of solid polyurethane strips bonded to the surface. They generally have a bulletlike shape and are often used for simple cleaning functions (wiping, drying) as unindirectional pigs. However, heavy-duty cleaning procedures, such as the removal of wax or other firmly adhering deposits can only be achieved by pigs with metal brushes.

Over to their size, pigs for pipelines are often multicomponent pigs (mandrel pigs): a central body system or mandrel can be equipped with various components (e.g., different disks, seal-

ing rims and cups, scrapers, and brushes). Worn parts can be exchanged in this way.

Pigs which do not consist solely of mechanical components (mechanical pigs), but also have some electrical/electronic parts are called intelligent (or smart) pigs. They are able to measure, to process, to store, or to transmit data. Smart pigs are used above all for in-line nondestructive testing of pipelines (e.g., magnetic flux leakage, ultrasound, and eddy current testing). With smart pigs, crack detection, leak detection, measurement and location of pipe defects, detection of corrosion and metal loss, and geometry measurement are possible. Photographic-inspection and video-monitoring systems are also available.

10. Safety

The risks that occur in pigging systems can be assigned primarily to three causes:

1) The kinetic energy of the traveling pig
2) The pressure and transient pulses caused by the propellant
3) Formation of explosive air – vapor mixtures when inflammable liquids are pigged with air.

These basic risks must be taken into account when a pigging system is planned. For further information, see [1] and [2].

11. Producers

Some major suppliers of pigging equipment in Germany are listed in the following:

– I.S.T. Pigging Technology GmbH, Schierenbergstr. 74, D-22145 Hamburg
– G. A. Kiesel GmbH, Wannenäckerstr. 20, D-74078 Heilbronn
– Pfeiffer Chemie-Armaturenbau GmbH, Hooghe Weg 41, D-47906 Kempen

1. Introduction

Superabsorbents are materials that can absorb up to 1000 times their mass of water. They are usually white, crystalline powders. When they come into contact with aqueous liquids, within a short period of time the powder changes into a gel-like substance and the liquid is absorbed. In this context the absorbency, however, depends very strongly on the type of aqueous liquid. In water dissolved ions in particular do strongly reduce the absorbency. Absorbents for non aqueous liquids are not part of the concept superabsorbents. The interested reader is referred to the relevant literature [1–4]

The development and commercial success of superabsorbents is closely connected with disposable diapers. Although the first superabsorbents were developed as water reservoirs for soils and as carriers for active ingredients, it was their use in diapers in the 1980s that helped in their breakthrough.

The first superabsorbents were polyacrylonitriles, grafted on to starch and subsequently saponified. Later, superabsorbents based on acrylic acid quickly gained recognition for economic reasons and due to their superior properties. A detailed overview on superabsorbents can be found in [5,6].

2. Definition

In the literature superabsorbents appear under different names. Hydrogel, polyelectrolyte gel, water-swellable polymer, water-absorbent polymer, superabsorbent material (SAM), and superabsorbent polymer (SAP) are the most frequent designations. Gross used the designation xerogellant, which describes both a dry gel and the behavior of the material [7].

Superabsorbents are capable of absorbing large quantities of aqueous fluids spontaneously and rapidly. The aqueous fluid is strongly retained and is not released mechanically. While swelling they essentially keep their original shape (Fig. 1). They only change in their dimensions and rheological behavior: a brittle solid material becomes a gel.

Figure 1. Superabsorbent particle after production and fully swollen in 0.9 % NaCl solution

Absorbency and Superabsorbency Absorption is a widespread common phenomenon. Besides surface adsorption there are two principal mechanisms of absorbence. One is the physical filling up of the open space of a porous media with capillary pressure as driving force. The other is diffusion of the liquid into the absorbent material itself. In this case the driving force is the difference in chemical potential inside and outside of the absorbent material.

The porous frame work of conventional absorbent materials, such as foams, absorbent papers, and textiles, can be formed by fibers, inorganic substances, or polymers. These materials can take up only a small amount of liquid. Liquids wet the surface and are transported to the interior by pores and channels. The extent and rate of absorption depend on the wettability, the pore volume, the length and radius of the pores, the viscosity and surface tension, as well as external forces such as gravitation and pressure differences. The transport of liquid through a porous material is commonly described by Darcy's law. It is valid for a linear and slow steady flow.

$$\frac{\mathrm{d}v}{\mathrm{d}t} = \frac{kA\Delta P}{\eta L_0} \tag{1}$$

The volumetric flow rate $\mathrm{d}v/\mathrm{d}t$ is given in terms of the cross-sectional area A of the sample, the length L_0 of the sample in the direction of flow, the permeability k of the medium, the viscosity η of the fluid and the pressure difference ΔP driving the flow.

Before superabsorbents were used, the absorbent cores of diapers consisted of only cellulose fluff or layers of absorbent papers. The main difference of these materials from superabsorbents is that they release most of the fluid under mechanical pressure. An extensive review of absorbent materials can be found in [8].

The absorbency of superabsorbents is chemical in nature. When an aqueous liquid comes into contact with a superabsorbent, it is spontaneously absorbed until the difference in chemical potential inside and outside the superabsorbent is balanced. The absorbed liquid can hardly be released mechanically. Water can only be removed from common superabsorbents by drying, applying high pressures, or deteriorating the solvent quality of water by adding water soluble salts or water miscible organic liquids.

3. Theory of Polyelectrolyte Networks

The majority of superabsorbents produced today are partially neutralized polyacrylates. Therefore, the theory of superabsorbents must deal with polyelectrolyte networks. They have long been studied, but a precise mathematical description is difficult and is still incomplete. The discussion of all the theories is beyond the scope of this article; for further information, see [9–12].

The most important commercial evaluation criteria of superabsorbents are the amount of aqueous liquid that can be absorbed, the rate at which it is absorbed, and the absorption of aqueous liquids under compression or under an external load. The theories try to relate the shear modulus G and the volumetric swelling ratio q to the structure of the polymer network. The structural parameters of a polyelectrolyte network are the number of cross-links per unit volume ν^*, the mean number of statistical segments between two junction points N, the interaction parameter between solvent and polymer chain χ, the molecular mass of the polymer chain per free counterion M_2, and the number of charges per polyion chain and their valences.

3.1. Elasticity

Superabsorbents are polyelectrolyte networks. Like other polymer networks they are rubber-elastic materials. Therefore, they are mostly described by models of rubber elasticity with additional ionic contributions. Modern theories use

the scaling concept for the description of polyelectrolyte networks.

The classical theories of rubber elasticity are based on the assumption that the total change in the free energy of the network's is composed cumulatively of the changes in free energies of the individual chains. There are two fundamental models, the model of the affine network [13] and the model of the phantom network [14]. In both models the polymer chains have no residual volume and therefore can interpenetrate unhindered. Whereas in the affine network model the fluctuation of the cross-links is suppressed completely due to the presence of the neighboring chains, the cross-links of the phantom network model can fluctuate around their mean position due to Brownian motion. Further developments of the phantom network [15–17] consider the influences of chain loops on the fluctuation of the cross-links. The model is also called the constrained junction model. As superabsorbents are generally cross-linked in solution, the swelling degree q_c, which was present during cross-linking must be considered. The relative swelling degree q_r is the swelling from the state of cross-linkage to the state of equilibrium.

$$q_r = q/q_c \tag{2}$$

The distribution of the chain-end distances is described in the simplest case by a Gaussian error function. In personal-care applications the polymer chains are not greatly extended because the swelling is limited due to the high ionic strength of the urine that is to be absorbed (see Sec. 3.2). Therefore, a Gaussian distribution leads to a good prediction of the dependency of the degree of swelling and the shear modulus.

$$G = A\eta\nu^* \mathrm{R}Tq^{-1/3}q_c^{-2/3} \tag{3}$$

R = general gas constant; T = temperature; A = structural factor, $A = (1 - 2/f)$, f = functionality of the cross-linker; and $\eta = \langle r^2\rangle_i/\langle r^2\rangle_0$ is the ratio of the end-to-end distances of cross-linked and free chains. The number of cross-links per unit volume ν^* can be calculated from the ratio of the concentration of cross-linker to monomer if the polymer network is ideal. In the case of superabsorbents, formation of the network by radical polymerization results in network defects. Besides loop formation and chain entanglements, chains are present that are attached to the network by only one link. Chains or small parts of the network which are not linked to the rest of the network can be extracted. The rate of extraction depends on the molecular mass and the degree of branching of the polymers. These extractable polymers do not contribute to the shear modulus but can contribute to swelling if they remain in the network during swelling. In addition the cross-linking density is normally heterogeneous, and the molecular mass of the chains between two cross-links M_c varies.

When polyelectrolyte networks swell strongly, the finite flexibility of the chains must be considered. Following the approach of Oppermann and Schröder [18], based on non-Gaussion chain statistics, the shear modulus G was obtained from the initial slope of the stress – strain equation [19]:

$$G = A\mathrm{R}T\nu^* q_c^{-1} q_r^{-1/3} \frac{1}{6}\left(\frac{L^{-1}(\gamma)}{\gamma} + \frac{\partial L^{-1}(\gamma)}{\partial\gamma}\right) \tag{4}$$

$\gamma = q_r^{1/3}N^{-1/2}$, L^{-1} = inverse Langevin function; $L(\gamma) = \coth\gamma - 1/\gamma$; $\eta = 1$.

The dependency of the shear modulus G on the swelling ratio q is influenced by the the number of elastic effective chains in the network ν^* and the mean number of statistical segments between two junction points N. N and ν^* can be evaluated by fitting the theoretical curve to the experimental data.

3.2. Swelling

When brought into contact with an aqueous fluid, cross-linked polyelectrolyte polymers swell and form a gel. The cross-linkage of the polymer chains hinders the dissolution of the polymer. The widening of the network decreases the degrees of freedom of the polymer chains of the network, that is, the entropy is reduced. With uncharged gels the entropy reduction is compensated by the energy which is generated by mixing polymer and solvent. The major driving force in the swelling of polyelecrolyte gels is the osmotic pressure due to fixed charges along the polymer chains and the free counterions which

are present when an aqueous liquid is added. An equilibrium between the gel phase and the surrounding solvent is reached, and the chemical potentials of all mobile components compensate each other.

The considerations are reduced to the chemical potential of the solvent water μ_1. In general three contributions are considered:

$$\Delta\mu_{1,\mathrm{mix}} + \Delta\mu_{1,\mathrm{elast}} + \Delta\mu_{1,\mathrm{ion}} = 0 \quad (5)$$

$\Delta\mu_{1,\mathrm{mix}}$ describes the mixture of the polymer with the solvents and results, in accordance with the Flory – Huggins theory [20] in the following relationship:

$$\Delta\mu_{1,\mathrm{mix}} = \mathrm{R}T\left[ln\left(1-q^{-1}\right)+q^{-1}+\chi q^{-2}\right] \quad (6)$$

The interaction parameter χ depends on the concentration, the temperature, and the pressure.

Hooper et al. developed a more realistic model for the interactions in polymer – water mixtures that considers hydrogen bonds and dipolar interactions [21]; however, it is more difficult to handle mathematically and contains further parameters which must be determined experimentally.

$\Delta\mu_{1,\mathrm{elast}}$ represents the expansion of the polymer network during the swelling process and can be described by the theories and assumptions on rubber elasticity [22, 23].

$$\Delta\mu_{1,\mathrm{elast}} =$$

$$1/3A\nu^{*}\mathrm{R}TV_{01}q_{\mathrm{c}}^{-1}q_{\mathrm{r}}^{-2/3}N^{1/2}L^{-1}\left(q_{\mathrm{r}}^{1/3}N^{1/2}\right) \quad (7)$$

To maintain electroneutrality, the charges along the polymer chains must be neutralized by the same number of counterions. This can lead to differences between the concentration of the counterions in the gel and in the surrounding solution. The concentration can only be balanced by diffusion of the solvent into the gel. This is the reason for the strong dependence of the swelling on the ionic strength of the surrounding solution. The lower the ionic strength the higher the degree of swelling. This behavior can also be explained using the Donnan equilibrium (→ Ion Exchangers, Chap. 6.1.), in which the phase boundary of the gel to the surrounding solvent is regarded as a kind of semipermeable membrane. If an anionic polyelectrolyte network is in a solution of a monovalent counterion and if the concentration of the ions c_{s} is used instead of the activities, this results in the following expression for the ionic contribution to the chemical potential $\Delta\mu_{1,\mathrm{ion}}$.

$$\Delta\mu_{1,\mathrm{ion}} = 2\mathrm{R}TV_{01}\left[c_{\mathrm{s}} - \sqrt{c_{\mathrm{s}}^2 + \left(\frac{r}{2qM_2}\right)^2}\right] \quad (8)$$

where ρ is the density of the dry polymer.

Further contributions to the description of the swelling behavior of ionic gels which are discussed in literature are the influence of the charges on the chains on the conformation and the stiffness of the chains, as well as additional electrostatic interactions. Since the charges on a polymer chain repel each other, the stiffness of the chain (the number of statistical segments N) is a function of the effective charge density and ionic strength in the gel at equilibrium.

More recent theoretical work describes the elasticity and the swelling behavior of polymer networks with scale arguments [24–26]. Rubinstein et al. [27] applied new discoveries about the relationship of chain configurations and the shear modulus G' on polyelectrolyte gels. These models describe the experimental data in part more accurately than the classical theories.

From the above equations it is difficult to derive an equation that directly relates swelling to the important parameters. Buchholz derived a simple equation assuming a network randomly cross-linked by a four functional cross–linker and neglecting the ionic effects [28].

$$q_r = \left(\frac{2kM_{\mathrm{c}}}{r_0\nu_{20}^{2/3}\left(1-3M_{\mathrm{c}}/M_{\mathrm{n}}\right)}\right)^{3/5} \quad (9)$$

$$k = \frac{(1/2-\chi)}{V_1} \quad (10)$$

ν_{20} = polymer concentration at the time of preparation during cross-linking, V_1 = volume of the swelling liquid, ρ_0 = density of the dry polymer, M_{n} = molecular wheight of the backbone, M_{c} = average molecular weight between junctions.

3.3. Phase Transition

Ionic polymer gels undergo discontinuous volume phase transitions in response to small changes in, for instance, temperature [29], sol-

vent composition [30], or when an external electric field is applied [31]. The collapse of polyelectrolyte gels in aqueous organic solvent mixtures has been studied extensively. Especially the effect of the pH and the ionic strength of the solvent on the phase transition was of interest [32, 33]. Prerequisite for the discontinuous volume phase transition is that the gel has enough positive internal osmotic pressure and that the solvent in which the gel is immersed is sufficiently poor [34]. The phase transition has been ascribed to the formation of ion clusters or ionomerlike conformations driven by the electrostatic attractions among ion pairs consisting of charged polymers and counterions [35].

Tanaka [36–38] used the Flory – Huggins formula and the Donnan equilibrium theory to describe the phase transition of polyelectrolyte networks. The occurrence and sharpness of the phase transition is characterized by the degree of ionization of chains in the gel f and the excess free energy of contact between polymer segments ΔF_s, which is influenced by the amount of organic solvent and added salt. When f exceeds a critical value f_c, the shrinkage of the gel with increasing amount of organic solvent becomes discontinuous.

$$\tau = -\frac{S_0 \emptyset_0}{r^2}\left[(2f+1)\,r - 2r^{1/3}\right] + 1 + \frac{2}{\emptyset_0}\frac{1}{r} + \frac{2ln\,(1-\emptyset_0 r)}{\emptyset_0^2 r^2} \qquad (11)$$

$$S_0 = u\nu/A\emptyset_0^3$$

$\emptyset$, $\emptyset_0$ = initial, final equilibrium volume fractions of the network, r = swelling ratio $\emptyset/\emptyset_0$, A = Avogadro's number, υ = solvent molar volume, ν = number of constituent chains per unit volume at $\emptyset = \emptyset_0$.

4. Chemistry and Production of Superabsorbents

The term superabsorbent is always used in connection with the absorption of aqueous liquids. Hence, modern superabsorbents are hydrophilic polymers. They are categorized into ionic and nonionic polymers, whereby the ionic polymers are further categorized into cationic, anionic, and amphoteric polymers. Acrylic acid is the basis for almost all commercial superabsorbents. They are generally manufactured by the cross-linking radical copolymerization of partly neutralized acrylic acid in water with a cross-linker having two or more polymerizable groups [39]. Linear polyacrylamides and poly(acrylic acids) are discussed in → Polyacrylamides and Poly(Acrylic Acids). The statements made largely also apply to the synthesis of cross-linked polyacrylic acids. For the synthesis of absorbent polymers based on other monomers, see [40–42].

4.1. Raw Materials

Monomers. Good polymer properties can only be attained with high-purity acrylic acid. Dimers of acrylic acid are formed during storage by Michael addition of one monomer molecule across the double bond of another. When the dimer is incorporated into the poly(acrylic acid) network the reaction can be reversed at high temperatures during the drying step, and one molecule of acrylic acid is cleaved off. Acrylic acid is typically inhibited with ca. 200 ppm of the monomethyl ether of hydroquinone (MEHQ). The effectiveness of MEHQ is increased in the presence of oxygen, which is added during storage but has to be removed to facilitate polymerization.

Besides acrylic acid, in principal all hydrophilic polymerizable substances come into consideration as monomers for superabsorbents. In addition, hydrophobic polymerizable substances can also be used as comonomers. Important for the superabsorbent effect is the generation of charges along the polymer chains when the superabsorbent comes into contact with aqueous liquids. Early superabsorbents were often graft copolymers whose graft base was a polysaccharide, especially starch [43]. Further possibilities are a partly neutralized copolymer of isobutene and maleic acid anhydride [44]; a saponified copolymer of acrylic acid and vinyl acetate [45]; a polyacrylonitrile, grafted onto starch and saponified [46]; a copolymer of acrylamide, 2-acrylamido-2-methylpropanesulfonic acid, and partly neutralized acrylic acid [47]; and a copolymer of acrylamide and trimethylacrylamidopropylammonium chloride [48].

Cross-Linkers. All compounds with at least two polymerizable double bonds, compounds with a polymerizable double bond and a functional group which is reactive towards the monomers, and compounds with at least two functional groups that can react with the monomers are generally suitable as cross-linkers for superabsorbents. Multivalent salts such as aluminum salts can also be used.

Preferably used are highly water soluble compounds such as *N*, *N′*-methylenebisacrylamide, triallylamine, di- or polyacrylic acid esters of polyols, (e.g., low-molecular poly(ethylene glycols) or ethoxylated trimethylolpropane), di- or poly(allyl ethers) of polyols, acrylic acid esters of mono(meth)allyl ethers, and di- or polyglycidyl compounds of polyols or polyamines [49–54].

4.2. Radical Solution Polymerization

4.2.1. Principles [see also (→ Polyacrylamides and Poly(Acrylic Acids, Chap. 3.1.)]

The polymerization rate of acrylic acid in aqueous solution depends on the pH of the solution and consequently on the degree of neutralization of the carboxyl groups [55]. At pH 7 the polymerization rate shows a minimum due to electrostatic repulsion between dissociated charged monomer and charged propagating radicals. Most commercial superabsorbents are sold with a degree of neutralization of between 50 and 85 mol %. Therefore, the low polymerization rate is either accepted or the superabsorbents are patrially neutralized after polymerization. Acrylic acid and the cross-linkers are dissolved in water. Smaller quantities of further co-monomers can be added. The partial neutralization of acrylic acid is normally carried out by addition of sodium hydroxide or sodium carbonate. After removing the oxygen from the solution, the polymerization is typically started with radical initiators. The so-called gel effect [56–59] in free radical polymerization at high monomer concentrations is associated with a slowing down of the rate of termination between active growing chains due to decreasing chain mobility, which leads to autoacceleration and high conversions as long as the momomer can be supplied to the growing chain ends. Due to the exothermic reaction and high reaction rates the gel point of the system is quickly reached, and the temperature rises to 100 °C and higher within minutes. Heat removal is necessary to avoid deterioration of the properties of the final product. The conversion of the polymerization has to be as high as possible, and all side reactions which increase the portion of residual acrylic acid monomer must be avoided.

In the co-polymerization of partially neutralized acrylic acid with cross-linkers bearing multiple vinyl groups, the time at which the cross-linker is incorporated into the growing chains depends on the reactivity ratios. Different kinds of functional groups in cross-linker molecule exhibit different reactivities. When the reactivity of the cross-linker with the monomer is high it is consumed early, so that the polymer chains formed late in the polymerization are less likely to be incorporated into the network. This results in extractable polymers which do not contribute to the modulus of the network. Therefore, cross-linker functionality should be available at the end of the reaction, too. Once the cross-linker molecule is part of the chain, the reaction of the other vinyl groups may be hindered or prevented.

Another possiblity of creating a polyacrylate network is to add substances to the polymerization mixture which can react with the carboxyl groups, such as multifunctional alcohols, glycidyl ethers, or multivalent cations.

Polymer chains that are not connected to the network through cross-linkers can be grafted onto the gel network by grafting reactions, especially at the end of the reaction or during drying. Peroxosulfates can abstract hydrogen atoms and can thus result in further cross-links. Extractable polymers can be formed by routes other than nonincorporation into the network; these include chain degradation and cleavage of cross-links. It is important to generate a homogeneously cross-linked network in which the extractable sol fraction is minimized. Network defects such as intramolecular cyclization, divinyl loops, chains with only one end attached to the network, and unconsumed cross-linker double bonds lower the cross-linking density and affect product quality.

When the polymerization is complete a gel is obtained, which is disintegrated, dried, milled, and sieved to the desired grain sizes.

4.2.2. Production Processes

In practice continuous and semi-continuous production processes are preferred. Acrylic acid, cross-linker, sodium hydroxide, and additives are mixed in storage containers. Consequently the order of the addition can vary. The amount of cross-linkers is between 0.1 and 2 wt % relative to acrylic acid. The degree of neutralization of the acrylic acid is 0 – 80 mol %. If a slightly neutralized acrylic acid monomer solution is polymerized the resulting polymer gel must be treated with an appropriate alkali to achieve the desired degree of neutralization [60]. The aqueous solution is freed from oxygen by purging with nitrogen in a stripper on the way to the reaction vessel or in the reaction vessel itself [61]. The reaction is started with water-soluble initiators. These can be thermal initiators such as peroxosulfates or azo compounds, redox systems such as iron salts and hydrogen peroxide, or photo-initiators. The initiators are metered into the reaction vessel or into the feed stream together with the monomer solution.

During the reaction a large quantity of heat is released. This limits the concentration of the acrylic acid in the monomer solution, which is typically between 15 and 40 wt %. A production process that operates with a high acrylic acid concentration of 50 – 80 % is also known. This process uses the heat of polymerization to evaporate water and gives a dry superabsorbent polymer in a slightly foamed form that has a water content sufficiently low for powdering without any further drying step [62, 63].

Because the throughput must be optimized for an economical process, attention is paid to good heat removal when selecting the polymerization vessels. Furthermore, as little water as possible should have to be vaporized during the subsequent drying step. Therefore, reactions vessels exist in which the gel being generated is disintegrated during the reaction [64, 65]. These kneaders can be equipped with different shafts. Another production process uses a belt [66]. The monomer solution is placed on a belt which is curved upwards in a U-shape at the sides. The initiators are metered into the inflow of monomer solution. After polymerization is completed the generated gel strand is cut into small blocks at the end of the belt [67]. The gel is further disintegrated to ensure optimum drying. Additives can be added to the disintegrated gel. Together with these steps further neutralization of the gel can be performed [68, 69]. In all cases the disintegrated gel is dried to a water content of 5 – 10 wt %. In principal, this can be carried out in all commercial dryers. Circulating belt dryers are preferred [70]. The temperature of the dryers is typically between 100 and 200 °C. The drying step also lowers the residual content of acrylic acid monomer. The acrylic acid evaporates together with the water vapor or reacts with residual initiator.

The dried product is milled and sieved. For use in diapers, normally a grain size between 0.15 and 0.8 mm is desired. Milling is usually carried out in two steps. After coarse milling in an attrition mill, knife mill, or roll crusher, the product is brought to its final grain size in roll crushers. Sieving is performed with tumbler or vibrating screens, whereby the overflow particles return to the milling circuit. The fine fraction is recycled back into the process by adding it to the monomer solution as a powder, as a suspension in a nonswelling solvent [71, 72] or by mixing it with the polymerized gel particles and water [73].

4.3. Inverse Suspension Polymerization

Superabsorbents produced by inverse suspension polymerization [see also → Polyacrylamide and Poly(Acrylic Acids), Chap. 3.2.2.] represent only a minor portion of the superabsorbents used commercially in diapers. Nevertheless, they have advantages and are predominantly used in technical applications such as cables.

The aqueous monomeric solution is prepared in the same way as for radical solution polymerization, but polymerization is then performed by dispersing the monomeric solution in a solvent which is inmiscible with the monomer solution, e.g., $C_6 - C_{14}$ aliphatic hydrocarbons. The initiator is soluble in the monomer solution and is usually added to it before dispersion. The polymerization is performed by heating the dispersion. To avoid coalescence and sticking together of the polymer particles during and after polymerization, a stabilizer is added to the continuous hydrocarbon phase before the suspension

is formed. Depending on the desired size of the particles, stabilizers can be nonionic surfactants such as sorbitan monostearate [74], polymers such as ethyl cellulose or oxidized polyethylene [75], as well as particulate suspension aids such as cationic bentonites [76]. The suspension aid used and the shape and rotating speed of the stirrer affect the shape and size of the particles. As a rule round particles are generated. By appropriate reaction control, however, agglomerated, porous, elongated, and convoluted particles can also be made [77,78]. Reprocessing is carried out either by filtration with subsequent drying or by azeotropic distillation to remove the water. Residual water and the continuous phase must finally be separated by drying.

Advantages of this method are a better heat dissipation during polymerization, the omission of gel disintegration and milling, and the possibility of modifying the surface of the particles directly afterwards in the same reactor. Disadvantages are that the continuous-phase solvents must be recycled. This is expensive, as they are volatile and highly flammable substances. Furthermore, the reactor dimensions are limited by the required stability of the suspension.

4.4. Surface Treatment

In the development of thinner diapers the superabsorbent partly had to take over the functions fulfilled by the cellulose fluff. The liquid distribution inside the diaper is hereby of central significance for using of the entire absorption capacity of the diaper. One problem with early superabsorbents was the tendency to clump when aqueous liquids were added. The liquid was hindered from penetrating further into the diaper, the diaper leaked, and the baby became wet. The gel particles were were soft and easily deformable, and the ability to swell under an applied load was low. For this reason modern superabsorbents for diapers are modified so that cross-linkage density at the surface is higher than inside the particles [79]. The corresponding test and the effects on swelling capacity and modulus of the gel are discussed in Chapter 5.

There are different ways to achieve a gradient of cross-linking density. Subsequent cross-linking of the surface with substances which can react with the carboxyl groups of the polyacrylic acid is mainly used. For example di- or polyalcohols [80], di- or polyglycidyl compounds [81], alkylene carbonates [82], or trivalent ions like aluminum ions [83] are used. The reaction is performed after spraying the substances onto the superabsorbent particles by a heat treatment at 90 – 250 °C in fluidized-bed, infrared, paddle [84], rotating-disk [85], or vortex dryers. A core – shell particle is obtained which, depending on the thickness of the shell, is vulnerable to attrition during handling.

A different method to achieve more extensive cross-linking of the surface is the addition of an oxidizing agent such as sodium chlorate to the polymerization, which during subsequent heating generates a gradient of cross-linking density from the inside to the outside [86]. In this case high temperatures are necessary, which can be detrimental to other properties.

5. Properties, Characterization, and Analysis

The demanded or required characteristics of superabsorbents depend very strongly on the application. For example, long-term stability in the swelled state or the ability to swell repeatedly is of minor significance for use in diapers, but for application in soils it is decisive. This chapter presents the fundamental tests for characterizing superabsorbents for hygiene products [87]. Particular requirements for superabsorbents for other applications are discussed in Chapter 6.

A superabsorbent is mainly characterized by its swellability, which depends on the structure of the network, that is, the cross-linking density, the modulus of the network, the charge quantity and density, and the completeness of integration of the monomers and the polymer chains in the network. As most superabsorbents are granules, characteristics of the bulk granules such as bulk density, particle-size distribution, shape, and surface constitution are of great significance in all tests. All tests are carried out with a large number of particles, as measurements on the individual grains are very expensive and seldom representative. This also means that the test results depend on the particle characteristics.

Figure 2. Centrifuge Retention Capacity (ERT 441.1-99) and extractable polymer (ERT 470.1-99) versus amount of cross-linker. The amount cross-linker relates to the content of acrylic acid.

5.1. Absorption Capacity

The absorption capacity of superabsorbents granules mainly depends on the density and homogeneity of the cross-linking of the polymer network, the number of charges on the polymer chains (degree of neutralization), and the ionic strength of the swelling. The higher the cross-linking density the lower the absorption and the lower the amount of extractable polymer (Fig. 2). The absorption capacity is usually determined gravimetricaly.

Ionic effects have a strong influence on the absorption capacity. The higher the charge on the polymer chain (i.e., degree of neutralization) and the lower the ionic strength of the swelling liquid, the higher is the absorption (Figs. 3 and 4). Trivalent cations reduce the absorption more than bivalent cations, which in turn are more effective than monovalent cations. As substitute for urine either a synthetic urine solution or, more simply a 0.9 % salt solution is used. The way in which the test is performed also affects the determined degree of absorption. As the test system consists of superabsorbent granules, a part of the liquid is not fixed inside the superabsorbent particle itself but between the individual gel particles (interparticle or interstitial liquid). If this liquid is removed by centrifuging or brief application of a vacuum, the fluid retention of the superabsorbent itself is obtained.

A standard test for the absorption capacity is the centrifuged absorption capacity CRC (ERT 441.1-99) which is the ratio of the absorbed liq-

uid to the mass of the dry superabsorbent. 0.2 g of superabsorbent granules are filled into a heat-sealable teabag, which is subsequently sealed. The teabag is weighed and then immersed in of 0.9 % NaCl solution for 30 min. Then it is transferred to a centrifuge (Fig. 5) and spun at 1600 rpm for 3 min, after which it is weighed again. The same procedure is carried out on a teabag without superabsorbent as a blank value. The retention is calculated from the weigh of the filled teabag after swelling and centrifugation m, the weight of the dry superabsorbent filled into the teabag m_s, and the and weigh of the empty teabag after swelling and centrifugation m_t.

$$\mathrm{CRC} = \frac{m - m_s - m_t}{m_s} \tag{12}$$

5.2. Shear Modulus

The viscoelastic behavior of a substance is measured by subjecting it to a harmonically oscillating shear deformation γ. The shear modulus G is determined from the shear stress σ. The shear modulus G can be defined as a complex quantity [88]:

$$G = G\prime + iG'' \tag{13}$$

where G' is the storage modulus and is a measure for the elastically stored energy, whilst the loss modulus G'' represents the energy which is dissipated by viscous flow.

A definition of a gel in terms of dynamic mechanical properties is that the storage modulus G' exhibits a pronounced plateau and the loss modulus G'' is considerably smaller than the storage modulus in the plateau region [89]. G' and G'' are measured with an oscillatory rheometer. Normally a plate – plate geometry is used. In practice, the pre-swelled superabsorbent granule is used. A defined grain fraction of the superabsorbent granule is pre-swelled to 70 – 90 % of the maximum swelling in 0.9 % NaCl solution. The pre-swelled granule is positioned on the lower plate. The gap between the plates is adjusted to the size of the gel particles. After lowering the upper plate, the gel particles which project over the edge of the plates are removed. An oscillating strain with a frequency of, e.g., 1 Hz is applied to one of the plates.

The swollen particles between the plates are in contact between each other. The shear modulus depends on the binding forces and the mobility between particles, and not only on the network structure of the gel. Therefore, the strain amplitude has to be very small, or measurements are carried out at different amplitudes and extrapolated to zero strain. Even then the method only gives meaningful results when the cross-linking density of the particles is not too low or high and when the particles are not surface-cross-linked. A more appropriate method is the use of a pre-formed disk of gel which fits perfectly into the gap between the plates of the rheometer. Such measurements [90] showed that in accordance with theory, the storage modulus increases with increasing cross-linker concentration (Fig. 6) or efficiency and with increasing monomer concentration in production. The

Figure 5. Centrifuge Retention Capacity (ERT 441.1-99)

Figure 6. Storage modulus (frequency 1 Hz, amplitude 1 mrad) of sodium polyacrylate gels as a function of the amount of cross-linker used in polymerization. 1 g superabsorbent powder (300 – 600 µm) was swollen in 50 mL of deionized water.

as-prepared degree of neutralization also influences the storage modulus but the direction is controlled by the cross-linker density.

5.3. Kinetics of Absorption

The rate at which a liquid is absorbed into the particle can be determined by measuring absorption versus time. The time required for a specified percentage of the maximum absorption to be reached is a measure of the rate.

In this test the superabsorbent must absorb the liquid from a reservoir. The data can be fit to a simple exponential [91]

$$\frac{\mathrm{d}q}{\mathrm{d}t} = k\left[q_{\max} - q\left(t\right)\right] \tag{14}$$

where $q_{\max}$und $q(t)$ are the absorption capacities at equilibrium and at any time t under the conditions of the experiment. The rate constant k depends on the diffusion coefficient of the liquid into the particle D and the radius of the particle r.

$$k = \frac{\pi^2 D}{r^2} \tag{15}$$

The diffusion coefficient depends on the temperature and on the salt concentration of the liquid.

Other test methods determine the time which a specified amount of superabsorbent requires to absorb a certain quantity of liquid after mixing (vortex test [92], dynamic swelling rate [93]).

The absorption rate can be improved by increasing the porosity of the particles and thereby increasing the contact area. This can also be achieved by changing the shape. Superabsorbent fibers exhibit very fast absorption. Since the absorption rate is higher for smaller particle, the formation of agglomerates of smaller particles increases the rate of absorption without changing the particle-size distribution.

The wettability of the particle surface influences the initial absorption. A hydrophobic coating delays the uptake of liquid. Since the tests are carried out with a large number of particles, properties such as the permeability of the granuler mass (or bulk) are important. This is influenced by the packing of the particles, which in turn is influenced by the shape and the particle-size distribution of the particles.

5.4. Swelling under Load

The requirement for superabsorbents to absorb liquids under external pressure resulted from their application in diapers, for which improved performance was observed for superabsorbent which were less easily deformed and deswelled by the weight of a baby. The magnitude of the deformation depends on the modulus, which in turn mainly depends on the effective cross-link density and the extent of swelling.

Using scaling theory Buchholz derived an equation [5] in which the swelling capacities Q_{e} and Q of a gel in the unloaded and loaded state are proportional to the modulus of the fully swollen gel G_{e} and the applied pressure P.

$$\left(\frac{Q_{\mathrm{e}}}{Q}\right)^{9/4} - \left(\frac{Q_{\mathrm{e}}}{Q}\right)^{1/3} \approx \frac{P}{G_{\mathrm{e}}} \tag{16}$$

Q is defined as the ratio of the gel mass to the dry mass of the polymer. The absorption capacity CRC used in industrial practice is the ratio of the liquid mass absorbed to the dry polymer mass. The equation states that at a given modulus G_{e} and therefore a given swelling capacity Q_{e} of the fully swollen gel, the swelling capacity in the loaded state is lower at higher loads. On the other hand, the magnitude of the deformation depends on the modulus, which in turn mainly depends on the effective cross-link density and the extent of swelling. Highly cross-linked particles with low absorption capacity are able to swell sufficiently under an external load. By modifying the surface to give a core – shell particle with a higher cross-linking density near the surface, superabsorbents particles could be obtained that combine absorption capacities both with and without an applied load (Fig. 7, see next page).

For the determination of the absorption under load (AUL [94]) or absorption against pressure (AAP [95]) a measuring device is used that consists of an acrylic glass cylinder which is closed at the bottom with a metal gauze (Fig. 8, see next page). A specified amount of superabsorbent granules is filled into this cylinder. The measuring cylinder can be loaded with different weights. Usually loads of 0.3, 0.7, and 0.9 psi (ca. 2.1, 4.9, and 6.3 kg/m^2) are used. The absorption of the liquid is performed by placing the cylinder onto a porous ceramic filter plate, which is covered with filter paper. The ceramic

Figure 7. Centrifuge Retention Capacity (ERT 441.1-99) and absorption against pressure (ERT 442.1-99, 0.7 psi load) as a function of the amount of cross-linker. The amount of cross-linker is related to the content of acrylic acid. The circles represent the centrifuge retention capacity of the samples, the triangles represent the absorption against the pressure of the samples and the squares represent the absorption against pressure of the surface treated sample.
0.7 psi $\approx$ 4.9 kg/m^2.

0.7 psi $\approx$ 4.9 kg/m^2.

filter plate lies in a tray which is filled to its upper edge with 0.9 % NaCl solution. After 1 h the cylinder is weighed again. The absorption under pressure is calculated from the difference to the initial weight and the weigh-in of the superabsorbent, including the liquid in the pores between the particles. The resulting absorption capacity under load is also dependent on the way in which the liquid is transported in the particle bed. The liquid can be transported through the galled particle bed by capillary forces as long as the porosity of the particle bed is high enough and the pores between the particles are connected. When the particles absorb liquid and start swelling, they soften and can be deformed more easily. Hence, the modulus of the gel network decreases with increasing liquid absorption. An applied load deforms the particles and blocks the pores to a certain extent. This restricts further liquid transport to diffusion through the particles themselves which is a much slower process. A high cross-linking density, especially near the surface, helps to prevent deformation.

5.5. Permeability

The distribution of the liquid in the diaper, that is, the transport of the liquid from the point of entry to the rest of the diaper is important to fully use the absorption capacity of the diaper. Modern diapers contain large amounts of superabsorbents. Therefore the swollen superabsorbent particle mass has to be permeable for additional liquid to be transported through the gel mass, particularly when a load is applied to the gel. Low permeablity means blockage of the gel for further liquid, and the diaper may leak. Permeability depends on the particle-size distribution, the free volume of the pores and the connection

between them, and the ability of the individual gel particles to maintain their shape in the swelled state under pressure. Permeability is a function of the porosity, geometry, packing, and modulus of the gel particles. The permeability is measured by swelling the superabsorbent granules under pressure in an acrylic glass cylinder with a bottom of metal gauze. The throughput quantity per unit time of the liquid through the gel under load is a measure of the permeability [96].

5.6. Test Methods

Test methods for superabsorbents recommended by the European Disposables and Nonwovens Association (EDANA) are listed in Table 1.

5.7. Stability of Superabsorbents

The thermal stability of superabsorbent polymers depends on the degree of neutralization. Poly(acrylic acids) undergo dehydration commencing at about 150 °C on programmed heating at 10 K/min, predominantly by formation of an intramolecular anhydride between neighboring pendent carboxyl groups. Decarboxylation of the anhydride becomes significant from about 250 °C, and major fragmentation of the modified backbone occurs above 300 °C [97]. At degrees of neutralization exceeding 50 mol % evaporation of tightly bound water, rather than anhydride formation, is the assumed route for weight loss at lower temperatures [98]. Fully neutralized sodium polyacrylates are thermally stable polymers that undergo degradation only above 380 °C. The volatile degradation products are mainly carbon dioxide and acetone. Small amounts of alkenes, ketene, higher ketones, and aromatic hydrocarbons are also formed. The residue consists mainly of sodium carbonate together with some carbon. Polyacrylates neutralized with other metals, especially transition metals, can show different degradation behavior [94]. Once swollen, the stability of the gel is significantly lower. Mechanical stress, heat, UV radiation, traces of radicals or metal ions like Fe^{2+}, Fe^{3+}, Cu^{2+} or Al^{3+} in combination with oxygen result in a breakdown of the gel structure and the increase of the water-soluble fraction within a short time.

6. Uses

6.1. Personal Hygiene Products

The main application area for superabsorbents is personal hygiene: infant diapers, adult care articles, and feminine sanitary napkins. More than 95 % of the superabsorbents are consumed in this area.

Table 1. EDANA recommended test methods (ERT methods)

Test method	Description	Reference
pH	pHh value of a superabsorbent dispersion	ERT 400.1-99
Residual monomers	content of extractable acrylic acid, HPLC	ERT 410.1-99
Particle size distribution	screens with different mesh sizes	ERT 420.1-99
Moisture content	weight reduction after 3 h at 105 °C	ERT 430.1-99
Free swell capacity	free swell capacity in saline solution	ERT 440.1-99
Centrifuge retention capacity	fluid retention capacity in saline solution following centrifugation	ERT 441.1-99
Absorption against pressure	determination of the capacity to absorb saline solution under a specified pressure	ERT 442.1-99
Flow rate	time for a given mass of superabsorbent powder to pass through a specified funnel	ERT 450.1-99
Flowability	mass of powder (g) per unit time (s) flowing through a specified funnel	
Density	determined by pouring a representative sample through a specified funnel into a density cup	ERT 460.1-99
Extractables	sum of the acid and salt groups of monomeric, oligomeric, and polymeric carboxylates extracted from the superabsorbent polymer in saline solution	ERT 470.1-99
Respirable particles	particles having a diameter of less than 10 µm, determined by using a laser light-scattering particle size analyzer	ERT 480.1-99

6.1.1. Diapers

Modern diapers can barely be compared with the fabric diapers of 30 years ago. Especially in industrial nations, the disposable diaper has become standard.

A typical modern diaper (Fig. 9) consists of a permeable cover layer (coverstock), a distribution system (distribution layer), an absorption layer (absorbent core) and an impermeable outer layer (impermeable back sheet).

Figure 9. Schematic of a baby diaper

The cover and distribution layers have the task of taking up the baby's urine and distributing it over a wide area of the absorbent core. These webs are usually hydrophilically treated nonwoven fabrics mainly made of propylene. The absorbent core should store the liquid without releasing it to the surface of the diaper, in order to ensure a dry diaper. In the simplest case the outer layer of the diaper is a water-impermeable polyethylene foil. Improved foils are air-permeable.

The absorption core consists of a mixture of cellulose fluff and superabsorbent granules. The cellulose fibers provide for good distribution of the liquid in the entire layer but can not effectively store liquid themselves. While in the past the fluff percentage was at 80 – 90 %, today it is only ca. 50 % (Fig. 10). Thus diapers became thinner and the density of the core was increased. When early superabsorbents were developed the main emphasis was on absorption capacity. Due to the low modulus of the network, they were soft and could be easily deformed. They tended to block the liquid at the point of entry, and this led to leakage of the diaper. The small amounts of fluff used make this negative effect even more pronounced. The increased amount of superabsorbents in the absorbent core required improved superabsorbent properties. Even with an overlying distribution layer the ability of the absorbent core to distribute the liquid throughout the entire core is essential for using the total absorption capacity. The cross-linking density and the gel strength were increased, absorption capacity was decreased. Superabsorbents with special properties, such as the ability to swell under an applied load, low or high absorption rates, or unusual particle sizes, led to improved diaper designs. Fast-running diaper machines and modern storage and conveying systems demand an adjusted flowability. Health and safety regulations require a low content of dust.

Figure 10. Change of fluff/SAP ratio in diapers since 1985

Diapers for the adult care area distinguish themselves in particular by the absorption capacity, which must be greater. The portion of cellulose fibers is also higher. Special superabsorbents were also developed for adult care articles. For example, superabsorbents with improved ability to reduce odors [99] are used in this area.

6.1.2. Feminine Hygiene Products

Feminine sanitary napkins mainly consist of a cover, an absorption layer, in which superabsorbents can ce incorporated, and an outer layer (coverstock, absorbent core, back sheet). Frequently pre-manufactured products, such as for example airlaid composites, into which the superabsorbent is incorporated, are used as absorption layers. Feminine napkins have to be very thin. Therefore, the particle size of the superabsorbent granules used is normally smaller than in diapers. Superabsorbent fibers are applied as

well. Menstrual liquids are more difficult to absorb than urine. They are viscous fluids consisting of water, salts, proteins, and blood cells. Protein and blood cells are too large to be absorbed by the superabsorbents. They are only adsorbed on the surface of the superabsorbent particles where they impede the absorption of water and dissolved salts.

6.2. Packaging Applications

The ability of superabsorbents to retain aqueous liquids has also found applications in food packaging systems. Prepacked meat and poultry packages have an absorbent pad containing superabsorbent granules or fibers which is integrated into the tray or glued to the floor of the tray. So-called soaker pads are also used during the transport of fish. The absorbent pad must be able to absorb all of the water when the ice used for cooling melts. The absorbing pads typically consist of an inner part and a coverstock. The inner part can be a mixture of cellulose fibers and superabsorbents, an air-laid composite, or a laminate containing nonwoven fabrics and superabsorbent granules or fibers. On the underside the cover can consist of a perforated foil or a hydrophilic fabric, and the upper side of a liquid-impermeable foil or a hydrophilic fabric. All components of these absorbing pads must be approved for the food use [100]. This also results in particular limitations for the chemical composition of the superabsorbents.

In addition superabsorbents are used in smaller quantities as refrigerants. The swollen gel is frozen as a laminate or directly packed in plastic bags. Superabsorbents are also used to absorb condensation water in packaging or thicken contaminated liquids in transport containers in hospitals.

6.3. Soil Conditioners

Horticulture, agriculture, and forestry are a wide application field for superabsorbents. Due to their ability to store water and nutrients for uptake by plants they are used as soil conditioners. Examples of applications in the horticulture area are the use in flowerpots for ornamental plants, the integration into golf courses or football grounds, landscaping of embankments, roof gardens, and noise barriers, as well as the use in planting holes for trees and bushes. In agriculture the superabsorbents are applied in seed and plant furrows to increase the water-use efficiency. The best results are achieved on sandy soils in arid areas, where the ability to store water and nutrients has the most positive effect on water management and growth. Yield increases could be achieved for almost all useful plants, such as wheat, corn, alfalfa, potatoes, asparagus, and tomatoes.

In reforestation superabsorbents provide for better root-taking of the young trees, a lower mortality rate, and therefore lower planting costs.

Applications in soils create special requirements for superabsorbents. They must swell and shrink under the soil conditions and remain stable for several years. Since soils contain large amounts of electrolytes, superabsorbents are required which are effective at high salt concentrations and in the presence of multivalent cations. Copolymers made of acrylamide and acrylic acid are mainly used.

A particularly interesting application is the possibility to store biologically active ingredients such as plant-protecting agents in superabsorbents and to apply them in this form [101, 102]. The controlled release of the active ingredients reduces the required amount of the agent by extending the duration of action. The number of applications can be reduced, harmful side effects can be diminished, and new possibilities of application for existing plant protectives can be created.

6.4. Cable Applications

Superabsorbents are used in cables to avoid the penetration of water into the cable when the cable sheath is damaged. Mostly superabsorbents are used which swell very quickly and prevent the water spreading inside the cable by forming a water-impermeable gel layer. Furthermore, this gel layer must be stable over a certain period of time. For applications in cables laid on the seabed, superabsorbents are required

Figure 11. Depiction of where superabsorbents can be used in a cable

which are insensitive to bivalent cations. Polymers with other monomers than acrylic acid are used, as well, i.e., copolymers of maleic anhydride and isobuthylene. Particle sizes between 45 and 300 µm are mostly used. The particles are normally fabricated in to water-blocking tapes [103, 104] by mixing the powder with a polymeric binder and applying it to a nonwoven fabric. The particles can also be incorporated directly into the gaps of the cable during production (Fig. 11) [105].

6.5. Civil Engineering and Construction

In the building industry superabsorbents are used in sealing materials. For example, superabsorbents made from maleic anhydride and isobutylene are incorporated in rubber sealing tapes, which are used in joints between concrete blocks to seal against water. Superabsorbents can be added to concrete, cement, mortar, or ceramics to achieve improved product characteristics such as extended setting time, lower water stress, or increased porosity. Until now, superabsorbents have only been used in specially products. There are numerous possible applications during the conditioning and thickening of mud. Positive results were obtained with secondary scale [106], paint sludge [107], and garbage-incineration ashes [108]. Industrial-scale implementation is currently hindered for economic reasons.

6.6. Other Applications

In medicine, small quantities of superabsorbents are used in wound dressings to improve healing in humid environments and in sticking plasters [81]. Superabsorbents are used for pet care as pet sheets and kitty litter. Other applications are in perspiration absorption in belts or gloves, as absorbents in portable toilets, as gelling agent in deodorants, and as additives in lotions. Hydrogels also act as sensors. They can swell or shrink spontaneously in response to changes in temperature, pH, or electric fields. They are even used as artificial snow. There is a hall in Tokyo where skiing is possible on snow made of frozen superabsorbent gels. Further applications are continually being discovered, so that this list cannot be complete.

7. Other Forms of Superabsorbent Polymers

Although superabsorbents are currently offered almost exclusively in the form of granules or powders, other forms such as fibers and foams can also be produced. Due to their characteristics and production costs their application is as yet limited.

7.1. Fibers

Superabsorbent fibers are an interesting alternative to granules. Due to their shape they can easily be processed with other fibers. The absorption rate is improved through the higher ratio of surface to volume. Disadvantages are the low mechanical stability, the sensitivity to humidity, their low bulk density, a low swelling ability under pressure, and the high production costs. Besides hygiene products, they are mainly used in technical products such as cables, filters, and packaging.

They are typically manufactured by spinning polymer solutions containing a cross-linker, whereby cross-linking is performed during drying. The fibers are subsequently cut. The polymers can consist, for example, of acrylic acid, an alkyl acrylate as softener, and a self-cross-linking monomer such as hydroxyethyl acrylate [110]. Cross-linking is performed during drying. Copolymers made of isobutene and maleic anhydride [111] with polyols as cross-linkers are also used. Another possibility is the surface modification of nonabsorbent fibers such as polyacrylonitrile fibers [112]. The addition of sodium hydroxide generates carboxylate groups, which impart absorbent characteristics on the fiber.

7.2. Foams and Films

Films of pure superabsorbent currently have no commercial significance. Polymer solutions or emulsions are available, which are applied to fibers or textile surface structures [113, 114]. The polymers are either self-cross-linking by heating or exposure to UV light, or a cross-linker is added. These polymers are based on the same monomers which are used for fibers or granules.

There are two different types of superabsorbent foams. First, the foam itself can consist of superabsorbent material, produced by foaming a monomer solution with subsequent polymerization [115, 116] or by thermal foaming of a polymer solution or emulsion, which can contain cross-linker, blowing agents, and other additives [117, 118].

Second, superabsorbent granules can be integrated into a foamed matrix. The foamed matrix is used for fixing the superabsorbent granule and distributing the liquid, but does not contribute greatly to the liquid absorption. The matrix can be, for example, a polyurethane foam [119]. Latex foams are also used [120, 121].

Special foams are known under the name HIPE (high internal phase-ratio emulsion) [122] which have very good absorbency characteristics, but strictly speaking are not superabsorbent. Their absorbency effect is based on the creation of a very dense capillary network. The monomers form the continuous oil phase of a water-in-oil emulsion. The aqueous phase is used as a place holder for the pores and is removed after polymerization by washing and drying. An open pore structure of low density is thus created. As hydrophobic monomers are mostly used, the surface must be chemically modified by introducing polar groups [123, 124] to enhance the wettability of the foam structure for aqueous liquids.

8. Environmental Aspects and Toxicology

Cross-linked polymers of partially neutralized acrylic acid are the main superabsorbent polymers. Therefore, they were tested in various systems to elucidate their toxicological profile both for handling during production and use in articles such as diapers [125, 126].

They are essentially insoluble in water, but they contain up to 10 wt % of water-extractable fraction and up to 500 ppm of residual sodium acrylate.

Superabsorbent polymers based on partially neutralized acrylic acid exhibit a toxicological profile of low concern. Under appropriate test conditions there were no signs of acute oral or dermal toxicity. Furthermore subacute oral toxicity and long-term dermal toxicity have not been observed in rats [127]. The eye-irritating potency (rabbit) seems very low. Absorption after oral uptake is negligible [128]. They show no evidence of allergic contact sensitization in guinea pigs and humans and no irritating properties. No mutagenic and teratogenic potency was found [129]. In a chronic inhalation study in rats, micronized fine dust of a superabsorbent polymer caused tumor formation in rat lungs at the highest concentration. This effect is attributed to a chronic inflammatory process and not to a direct genotoxic action [130]. However, the use in

consumer products and technical articles must be regarded as safe.

Superabsorbent polymers will eventually enter the environment via different routes and in various forms like exhaust gas after incineration of household waste (diapers, etc.), compost, household waste in landfills, or biosludge, which is incinerated, landfilled, or used in agriculture. Taking realistic predicted environmental concentrations and the ecotoxicity data into account there is no concern for the environment.

Pollution of ground water is highly unlikely as extracts strongly bind to the soil matrix with only little desorption and subsequent leaching of a very small mobile fraction of low molecular mass which seems to be potentially biodegradable [131].

Biodegradability studies in aquatic systems show that superabsorbent polymers based on partially neutralized acrylic acid are poorly biodegradable. In soil there is a potential for biodegradation once the polymer is water-soluble. In an optimized simulation of an intensive aerobic composting process a superabsorbent polymer was degraded by 14 % after 45 d. The metabolism of the aqueous soluble fraction of a superabsorbent polymer in soil was monitored under aerobic conditions. 20 % degradation to CO_2 resulted after 39 weeks. In a recent study white-rot fungus could both solubilize and mineralize the polymer in the soil. Soil microbes alone were not able to degrade the polymer but cooperated with the fungus during polymer degradation in soil [132, 133].

9. Economic Aspects

Superabsorbents are used almost exclusively in personal hygiene products. World consumption in 2001 was 1 100 000 t. Of this 83.5 % went into diapers, approximately 8.5 % into adult care articles, 5 % into feminine sanitary napkins, and 3 % into other applications. The industry is concentrated in a few companies, both in personal hygiene products and superabsorbents. There are two major manufacturers of diapers (Kimberly-Clark, Procter & Gamble) and four major manufacturers of superabsorbents (BASF, Nippon Shokubai, Dow, Degussa).

Worldwide market growth is estimated at 5 % per year, whereas for North America, Europe, and Japan no market growth is assessed. In 1995 [134] consumption was only ca. 700 000 t/a. The rapid increase since then can be explained mainly by the increased amount of superabsorbent in diapers, which made the development of thinner diapers possible. Diapers reduced in volume not only have esthetic appeal, they also make economical sense. Besides production costs, packing, and transport costs are reduced. Whether the quantities will increase any further is not yet clear. The future increase in superabsorbent production for the personal hygiene market is certainly connected to the growth of the markets for diapers in Eastern Europe, South America, and Asia. However, at the same time, the use of superabsorbents for technical applications is only just beginning.

1. Introduction

Energetic ions and ion beams are very flexible tools being used in material research, biology and medicine, microelectronics and micromechanics, optics, analysis, and basic research. For most of these fields they provide a certain breadth of applications. In some areas like microelectronics they also play the role of a key technology. The connection and network formation of the ion technology with different areas of science, applications, and materials is shown schematically in Figure 1. Special advantages of ion beams are the flexibility of size ranging from focused beams (≤ 1µm to broad beams ≈ 1 m wide. The penetration depth of the ions in the material ranges roughly from 0.3 nm to 10 µm and depends on their energy. Finally, the beam can consist of ions of nearly any element from hydrogen to bismuth. Because of the possible energy variation from several electronvolts up to 10^9 eV, the differences in mass, and the specific chemical properties of the ions, a huge number of variations exist to generate physical, chemical, or biological effects or analytically useful signals. Ion beams represent an excellent and flexible tool for surface modification of small samples or for basic and applied science applications. In industry they are used for semiconductor processing and for niche applications in different materials finishing procedures. Treatment of large areas is under development but not yet ready for industrial use. Finally, ion beams may be used for analysis of thin films and surfaces (⟶ Surface and Thin-Film Analysis – Static Secondary Ion Mass Spectrometry (SSIMS)).

Figure 1. Connection and network formation of ion beam technology with different areas of science, materials, and application

In the following at first the basics of the interaction of ions with solid materials and the principles of the different ion beam techniques will be described (Chap. Interaction of Ions with Matter). Then a short survey on the necessary equipment and tools will be presented (Chap. Equipment for Ion Beam Generation and Application). In Section Semiconductor Processing . the applications of ion beams for the processing of semiconductors are briefly reviewed. More details are given in Semiconductors – Wafer Fabrication.

Sections Metal Modification and Ion Beam Modification of Insulators deal with the application of ion beam techniques in the modification of metals and insulators, respectively, with special emphasis on features such as wear, friction, corrosion, adhesion, conductivity, and the corresponding microstructural changes. In Chapter Outlook some ideas about future trends will be presented.

For a general introduction into the ion beam technique see [1], [2], [3], [4], [5], [6] and the

2. Interaction of Ions with Matter

An energetic ion beam impinging on a solid surface may lose its energy by a number of processes [1], [7]:

1. Electronic excitation of the target atoms (so called electronic stopping).
2. Elastic collisions with the nuclei or atoms of the targets (so called nuclear stopping).
3. Charge exchange and inelastic collisions.

In the energy regime relevant for the applications of ion beam techniques the processes (1) and (2) are of major importance. In the *electronic stopping regime*, the ions (low mass and higher energy) travel straight through the bombarded material, in the nuclear regime (lower energy, higher mass) the collisions lead to strong directional spread.

To give an example: An (α-particle (He ion) of 1 MeV energy loses ≈ 99.9 % of its energy by electronic stopping, an Xe ion of 100 keV energy ≈ 90 % by nuclear stopping.

The straggling of the ions during the slowing down process is responsible for a theoretically Gaussian distribution of the stopped ions in the bombarded material. The half width of the distribution as well as the range depend on the mass and energy of the ions and on the target material. The range is usually expressed as projected range defined as the position of the maximum of the Gaussian curve with respect to the target surface. Referring to the examples given, the projected range of 1 MeV He^+ in Al is 2.6 ± 0.12 µm and of 100 keV Xe^+ only 40 ± 11 nm. The detailed values for most ions and materials may be found in tables or can be calculated by the TRIM code (a computer code based on the LSS theory performed by Lindhard, Scharff, and Schiøtt [10]) [8].

The two dominant stopping modes may cause a number of modifications in the bombarded materials.

- Chemical changes such as cleavage or formation of bonds in compounds.
- Heating of the target.
- Doping or alloying with the implanted ions.
- Generation of various types of defects.
- Enhanced diffusion (surface and bulk).
- Densification of the bombarded region.
- Phase changes and formation of special textures and surface morphologies.

Of special importance is the *sputtering effect*, namely the emission of surface atoms from the target as a consequence of the nuclear stopping process near the surface [2]. Therefore, the sputtering rate is high for low to medium energy of the beam, high ion mass, and low target binding energy. In some cases one impinging ion may sputter 10 – 100 target atoms. Consequently the sputtering process can be used for surface ablation and surface cleaning.

The intensity of the interactions naturally increases with increasing ion dose or ion fluence, expressed as ions/cm^2. Above 10^{12} ions/cm^2 chemical changes and defect formation near the surface of the target can be effected. At fluences around 10^{15} ions/cm^2, modifications of the crystal structure, surface morphology, and electrical properties takes place, and above 10^{15} ions/cm^2 the mechanical surface properties are affected, substantial surface ablation and degradation occur, and the doping and compound formation level approaches the percent regime [3], [9].

As compared with the impact of electrons and photons, ions show the following differences and advantages.

1. Ions interact much more strongly with the target than electrons and photons.
2. The interaction depth of ions is restricted to a few micrometers, however the limits of the interaction zone are sharp and very well defined. There is nearly no depth straggling or interaction zone broadening as in the case of electrons.
3. Ions can be focused to spots < 1 µm allowing direct nanostructuring of surfaces.
4. Ion beams are universal doping tools because any stable ion can form a beam and the energy may be varied from several electronvolts to several megaelectronvolts.

Figure 2. maps schematically the most important basic applications of ion beams. The analytical applications mentioned in the figure are treated in a different keyword (⟶ Surface and Thin-Film Analysis – Static Secondary Ion Mass Spectrometry (SSIMS)).

Figure 2. Schematic of the most important properties of the “tool” ion beam

Material modification with ion beams may either be performed by direct bombardment of the subsurface region or by creating a new surface under bombardment by sputtering or by ion assisted deposition. The different techniques are illustrated in Figure 3. [10]:

1. Ion implantation for modifying or doping a region of typically ≤ 1 µm below the surface.
2. Ion beam mixing for improving the interface between an already existing coating and the sample by intermixing and densification (usually restricted to layers ≤ 1 µm thick). For these two techniques an ion implanter or ion source is required that delivers ions of 100 keV – 1 MeV.
3. Ion beam assisted (enhanced) deposition (IBAD). An element or compound is deposited from the gas phase and simultaneously bombarded with an ion beam. This improves the adhesion to the sublayer and densifies or modifies the coating. By choosing the right deposition parameters the structure and texture of the growing film can be affected in a controlled way as compared with pure evaporation. If an element is deposited and the ion beam consists of reactive species or if a reactive gas is fed to the surface during bombardment the coating may be transformed into a compound (Cr + N^+ beam ⟶ Cr_XN, Ti + N_2 + Ar^+ beam ⟶ TiN; see also Nitrides – Boron Nitride).

Figure 3. Different ion beam techniques: ion implantation, ion beam mixing and ion beam assisted deposition compared with pure evaporation

For IBAD ion sources are required, that generate low- to medium-energy ions, and an apparatus for evaporating elements and compounds. Some possible combinations are presented in Figure 4.

Figure 4. Possible combinations of depositing a coating under ion bombardment (IBAD)

In the case of a focused ion beam or by using masks, structuring or local treatment of a surface is possible as shown in Figure 5. Ions of higher energy may also penetrate deeper into a material, as illustrated in the lower part of Figure 5. This effect can be used for destruction of degenerated tissue for medical purposes or formation of deep implanted layers for microelectronics applications.

Figure 5. Use of focussed and high energy ion beams for A) microstructuring (µ-focussed treatment and alloying < 1 µm); B) formation of deep implants; C) destruction of local regions of tissue

Techniques, which are comparable to ion implantation and IBAD, are plasma immersion ion implantation (PIII) and ion plating [11]. In the case of *plasma immersion implantation* the sample is not bombarded by an ion beam but by ions generated in a plasma. This is performed by giving the sample a pulsed negative bias of several 10 kV. Plasma immersion implantation is less flexible than ion implantation, however, three-dimensional or shaped samples are easier to treat. The advantage of IBAD over ion plating and comparable physical vapor deposition (PVD) techniques (see Thin Films – Physical Vapor Deposition (PVD) Processes) is its lower working pressure and the precise control of the energy, direction of incidence of the ions, and within certain limits also the treatment temperature. However, a disadvantage is the difficulty to treat bigger and odd-shaped items.

[Top of Page]

3. Equipment for Ion Beam Generation and Application

Equipment for ion beam generation and application usually consists of a vacuum chamber, where the beam is formed, and a target station. The probably most important part of an apparatus for ion beam modification is the ion source [4, 5, 12]. An ion source is an ion reservoir from which ions are extracted and form a directed ion beam.

3.1. Gaseous Ion Sources

Here, the reservoir usually is a plasma which is confined in a certain volume. The plasma is sustained by ionized gaseous species, preferably the ones which form the ion beam. However, there may also be an auxiliary gas forming the main part of the plasma while the species of interest is only diluted in it. The most important part of a gaseous ion source is the plasma generator which is basically a vacuum vessel filled with a gas to a certain pressure at a controlled flow rate by means of a valve from an external gas reservoir. Figure 6. shows a schematic presentation of a typical ion source.

In order to ionize the gas atoms or molecules, energy has to be supplied to the gas. A number of processes can be used for ionization. The most common one is electron impact. Electrons are accelerated in an electrical field to kinetic energies high enough to overcome the first ionization potential of the gas particles when they encounter the particles. The electrons can be supplied thermionically by a hot filament. A wire, often made of tungsten or tantalum, is electrically heated to a temperature high enough to emit electrons. In an electrical circuit, this filament acts as cathode, while another part of the ion source, often the vessel itself, acts as anode. Thus, an electric field is established in which the electrons are accelerated. This is the principle of *hot cathode ion sources*.

In *cold cathode ion sources*, ions impinging on the cathode create secondary electrons which in turn are accelerated in the electrical field and ionize the gas. Here, an externally induced ionizing process has to take place in order to ignite the discharge. Often, cosmic rays are sufficient for this purpose.

Mostly, the plasma is confined in a magnetic field. The field elongates the path of the ionizing electrons by forcing them into a spiral movement, thus increasing the number of collisions with gas particles and hence the number of ions.

Apart from electron impact, electromagnetic waves, e.g., *radiofrequency* (rf) waves can be used for ionization. The rf power is coupled inductively or capacitively into the gas volume. The radiofrequency energy excites the particles which become ionized in collisions. In *microwave* ion sources, another wavelength regime often used, electrons absorb the microwave energy and become accelerated to energies high enough for ionization. Further methods of ionization are surface ionization, field ionization, photoionization, spark ionization, etc.

Once ions have been created, they have to be formed to a directed beam. For this purpose, an extraction system is used. An external electrode near the plasma boundary is negatively biased with respect to the plasma and accelerates ions out of the plasma. The extraction electrode is supposed to extract the ions from the plasma, but not to collect them. For collection of ions it contains an aperture. The ions move towards the electrode and through the aperture and then drift on. Thus, an ion beam is formed.

For generating ions of gaseous species in the described way, a number of different ion sources are available. Apart from the kind of ionization, there are other types of classifications which can be applied to ion sources. One is to distinguish sources for narrow but dense ion beams from sources for broad beams, another one makes a distinction between ion sources designed for accelerating the ions to high energies and those which emit low energy ions.

The most prominent source for broad beams of low energy ions is the Kaufman type ion source (see Fig. 6). It is a hot-filament ion source with a large-volume plasma chamber where the ions are extracted by a multi-aperture system. Rather than using an extraction electrode with a single drill-hole, as described below, a large-area grid is used. In this way, an ion beam with a diameter up to several tens of a centimeter can be generated. Another type of ion source capable of creating large area ion beams is the above mentioned radiofrequency-driven source. In contrast to the hot cathode ion sources, which contain one or several filaments made of an oxidizable metal, an rf driven source may be operated with reactive gases such as oxygen or hydrocarbons.

Figure 6. Schematic cross-section of an ion source (hot cathode type for gaseous ions)

Most types of large-area ion sources require a multi-aperture (grid extraction) system. In the end-Hall ion sources, the expensive extraction grids are replaced by a potential difference generated by a magnetic field and a strong electron current.

As mentioned before, the beam shape is determined by the extraction system. Most broad-beam ion sources and focused beam sources, both for low and high energy ions, are equipped with a circular extraction system. These sources emit a circular symmetric ion beam with either a bell-shaped intensity distribution in cross-section of the beam, or with a beam with a more or less flat plateau in the center. When flat elongated workpieces or coil material are to be processed, elongated extraction systems for line-shaped ion beams up to several 10 cm in length are available. In this case, the workpiece is moved through the ion beam. These systems, also called sheet or ribbon beam ion sources, may be scaled-up to a length of 1 m or more.

Broad beam ion sources are used when the beam is directly applied to the workpiece to be modified. However, when the beam has to be guided, swept, or manipulated, its diameter is restricted. In this case, different ion sources with narrow extraction systems have to be used. These sources include the Penning ion gun (PIG) which is of the cold cathode type and therefore capable of generating reactive ions, the Duoplasmatron ion source of the hot cathode type with a particularly intense ion beam with a small diameter (⟶ Surface and Thin-Film Analysis – Ion Sources), the hot-cathode CHORDIS with a comparatively large volume and powerful beam, and the Freeman ion source. These ion sources have typically a single aperture extractor which may be round or elongated. The Freeman source is usually equipped with a slot-shaped extractor.

3.2. Solid Sources

With gaseous feeds, ions of solid materials can only be generated by a molecular species, e.g., B_2H_6, when boron ions are required, or CO for generating carbon ions.

However, in some of the above mentioned ion sources also solid feed materials can be used, namely in sputtering sources and in oven sources. A typical example for the latter is the Freeman ion source in the oven version. In the plasma vessel an electrically heated crucible is placed, out of which solid material with a sufficiently high vapor pressure can be vaporized. Metals such as silver or copper are thermally evaporated into a plasma of an auxiliary gas, mostly argon. Part of the evaporated metal atoms are ionized and can be extracted together with ions of the gas. Another possibility is to use an additional cathode made of the solid material to be ionized. Ions of the auxiliary gas are accelerated towards the cathode, impinge onto it and sputter atoms into the plasma. There, again, the metal atoms are ionized and can be extracted. In this way, ions of metals with a low vapor pressure, such as refractory metals like Cr or Ta, can be generated. Sputtering devices are available in a number of source types, including Duoplasmatron and Penning ion source.

To form an ion beam from a solid without auxiliary gas plasma, metal vapor vacuum arc (MEVVA) ion sources may be applied. Figure 7. shows a schematic cross-section. In this source, an electrical arc is drawn to a cathode. The cathode material is vaporized and forms a high-intensity plasma. These ion sources may also be used for generating broad beams when a broad beam extractor is used. MEVVA ion sources are usually operated in a pulsed mode, in contrast to other ion sources which mostly work in the d.c. mode.

Figure 7. Schematic cross-section of a metal vapor vacuum arc ions source for metal ions

A problem with ion sources operating with auxiliary plasmas is that, as mentioned before, a large number of ions of the auxiliary gas are extracted together with the desired ions of the solid material. Also a certain amount of ions from the ion source construction material may be present as impurity. For this reason, the ion beam has to be purified [6]. This is mostly achieved by means of a sector magnet working as a mass analyzer. When ions with a defined kinetic energy travel through a magnetic field, they are separated according to their mass differences. Light ions are strongly deflected in the magnetic field, while heavy ions follow a smaller deflection radius. By choosing a suitable magnetic field certain ionic species can be selected and pass the magnet, while others impinge on metal plates inside the tube. Another possibility for mass separation is to use a velocity filter based on the Wien principle.

Consequently, ion implantation facilities can be divided in those with mass separation and those without mass separation. Figure 8. shows a schematic representation of a set-up without mass separation. Ions are extracted from a large-area ion source and are accelerated towards the workpiece. For a uniform treatment, the workpiece usually has to be manipulated in the ion beam, e.g., by *x-y* rotation or motion. In case of an implantation facility with mass separation, an ion beam-line

has to be established (see Fig. 9). The ion beam is extracted from the ion source and passes the magnet. After separation, the desired ionic species is accelerated to high kinetic energies by applying a high voltage between the ion source/separation magnet and ground. To this end the ion source is kept at a positive high voltage with respect to the workpiece which is at ground level. Another possibility is to first accelerate the ions and then carry out the separation. In both cases, a beam of highly energetic ions — with kinetic energies from typically several 10 keV up to several megaelectronvolts, depending on the application — is generated. Usually, the ion beam-line contains beam-focusing and deflecting elements such as quadrupoles, Einzel lenses, and electrostatic deflection plates. The ion beam can be focused to a thin intense beam or defocused to a beam with a larger diameter. For a uniform treatment, the ion beam may be electromagnetically or electrostatically scanned in *x*- and *y*-direction and/or the workpiece is moved.

Figure 8. Schematic presentation of broad-beam ion implantation facility (without mass separation)

Figure 9. Ion implantation facility with a beam line with mass-separation and ion beam guiding elements

The implantation dose is usually determined by means of measuring the ion current integrated over the process time. Ion beam charge collection is done by a Faraday cup or directly on the conducting workpiece with suppression of secondary electrons.

The workpiece holder is usually a metal plate which can be cooled by water or heated resistively or by IR radiation. Often, it is mounted on a moving facility which allows *x/y*-motion or rotation by means of electromotors. For laterally defined ion irradiation, usually a beam collimator plate with a round or rectangular aperture is mounted in front of it.

All the vessels and tubes are made of vacuum-compatible material, usually with stainless steel seal. For generating the vacuum required for ion beam transport, different types of vacuum pumps such as turbomolecular, oil diffusion or cryopumps, combined with forepumps such as rotary pumps are used. The residual gas pressure is measured by means of Pirani, Penning, membrane, or other vacuum gauges.

3.3. IBAD Facilities

A facility for ion beam assisted deposition is in principle a set-up for broad beam ion implantation, combined with a vapor deposition device (see Fig. 10). Mostly, electron beam evaporation is used because of the versatility and high power input. Electron beam heating allows for vaporizing materials with high melting point and low vapor pressure, both elements such as titanium or carbon, and compounds such as oxides or nitrides. In analogy to the above described sputter ion sources, vaporization can also be achieved by using a secondary ion source which sputters material onto the workpiece (see Fig. 11).

Figure 10. Cross-section of an apparatus for ion beam assisted deposition with electron beam evaporator and ion source

Figure 11. Apparatus for ion beam assisted deposition with one ion source for sputter deposition and another one for ion irradiation of the deposit

Apart from electron and ion irradiation, the materials can also be evaporated electrically by resistive or inductive heating, or by irradiation with intense light (laser).

In IBAD facilities, in addition to gas pressure and ion flux measurement, the deposition rate has to be determined. This is

usually achieved by depositing the film onto microbalances of the quartz crystal monitor type, mounted close to the workpiece, or by measuring optically the atomic vapor density over the crucible. Another possibility is to monitor a property of the deposited film related to its thickness such as its resistivity. Ion and atom measurements define the ion to atom arrival ratio (I/A), an important quantity for IBAD deposition.

In addition to simple IBAD facilities with one ion and one atom source, more sophisticated ones exist with several sources for vapor and ions, these are used particularly when multi-component multi-layer films have to be deposited.

The process chambers for workpiece handling range from volumes of several 10 liters up to cubic meters. The corresponding workpiece holders have sizes up to 1 m^2 capable of handling workpieces up to several 10 kg load.

Facilities for ion beam treatment require specific safety considerations with respect to high voltage and electron induced X-rays. Usually, interlocks and shieldings are used for preventing these hazards. Additionally, toxic feed materials for ion source or evaporator may cause problems. Appropriate gas handling, exhaust and cleaning procedures and devices have to be applied.

For details on ion sources and ion implantation facilities see [4-12, 6].

[Top of Page]

4. Applications

4.1. Semiconductor Processing (⟶ Semiconductors – Wafer Fabrication)

Semiconductor processing is the by far most widespread and important industrial application of ion beam technology. For fabrication of electronic elements the semiconducting material has to be doped, i.e., a small amount of an impurity has to be introduced. Two methods for doping are used, one being diffusion where the dopant is introduced into the semiconductor by thermal motion, the other one being ion implantation. The latter has become more and more important and now plays a greater role. The unique features of ion implantation such as a very good reproducibility and versatility and the possibility to circumvent to a certain extent the restrictions of thermodynamics in order to create uniformly doped regions renders it an excellent tool for well defined doping. Nowadays, worldwide several thousand ion implanters are being used for semiconductor processing. Without ion implantation, the present state of semiconductor technology and the extremely widespread application of semiconductors would not have been reached.

By combination of different technological steps, with ion implantation being the doping step, microelectronic integrated circuit chip technology (IC) is realized. IC manufacturing includes wafer fabrication, wafer probing and sorting, chip assembly, chip testing and burn-in. Both passive electronic elements, namely resistors and capacitors and active circuit devices such as transistors are fabricated in large numbers on a wafer by doping of selected areas by means of ion implantation. The selected areas are produced in a multi-step process by lithography thus creating a desired pattern. The parts which are left free by the mask are doped. The ion beam is directed towards the surface and forms the electronic element in the desired shape and region of the wafer.

The development of IC technology included bipolar transistors and metal-oxide-silicon (MOS) transistors, later, for more power efficiency, complementary MOS technology (CMOS) was established. With this technology, static or dynamic random access memories (SRAMs or DRAMs) are fabricated.

Ion implantation is used for standard CMOS applications, including threshold voltage adjust implants, *n*- and *p*-well implants, field isolation implants, source/drain implants, lightly doped drain implants, punchthrough stop implants, polysilicon doping and others. Advanced applications include ultrashallow source/drain junction formation, channel and drain optimization, trench capacitors and other three-dimensional structures. Figure 12 illustrates the implanted regions and their functions.

Figure 12. Standard ion implantation applications for CMOS technology

Implanted Regions nd their Functions:
